Abstract
The ITER baseline scenario, with 500 MW of DT fusion power and Q = 10, will rely on a Type I ELMy H-mode and will be achieved with a tungsten (W) divertor. W atoms sputtered from divertor targets during mitigated ELMs are expected to be the dominant source in ITER. W impurity concentration in the plasma core can dramatically degrade its performance and lead to potentially damaging disruptions. Understanding the physics of the target W source due to sputtering during ELMs and inter-ELMs is important and can be helped by experimental measurements with improved precision. It has been established that the ELMy target ion impact energy has a simple linear dependence with the pedestal electron temperature measured by Electron Cyclotron Emission (ECE). It has also been shown that Langmuir Probes (LP) ion flux measurements are reliable during ELMs due to the surprisingly low electron temperature. Therefore, in this paper, LP and ECE measurements in JET-ITER-Like-Wall (ILW) unseeded Type I ELMy H-mode experiments have been used to estimate the W sputtering flux from...
divertor targets in ELM and inter-ELM conditions. Comparison with similar estimates using W I spectroscopy measurements shows a reasonable agreement for the ELM and inter-ELM W source. The main advantage of the method involving LP measurements is the very high time resolution of the diagnostic (∼10 μs) allowing very precise description of the W sputtering source during ELMs.

Keywords: tungsten sputtering, edge localized mode, magnetic confinement fusion

(Some figures may appear in colour only in the online journal)

1. Introduction

The ITER baseline scenario, with 500 MW of DT fusion power and Q = 10, will rely on a Type I ELMMy H-mode, see [1]. Partial divertor detachment with nitrogen (N), neon (Ne) or argon (Ar) impurity seeding will also be required to maintain the inter-ELM power load at manageable level. Tungsten (W) is the material now decided for the divertor plasma-facing components from the start of plasma operations. Under the partially detached divertor conditions envisaged for ITER, W atoms sputtered from divertor targets during mitigated ELMs are expected to be the dominant impurity source. In ITER, W impurity concentration in the plasma core above 5 × 10⁻⁵ can degrade fusion performance and may lead to potentially damaging disruptions, see [2]. Understanding the physics of W contamination in the plasma core is important and a primary input for this is the target W source mainly due to sputtering during ELMs.

The JET-ITER-Like-Wall (JET-ILW) [3] comprises a W divertor and beryllium (Be) main chamber wall thus matching the material configuration planned for ITER. Due to the high energy threshold for physical sputtering of W by deuterium ions (D⁺), the dominant Be ion species, Be²⁺, contributes to W sputtering in the divertor between ELMs (inter-ELM), see [4]. During ELMs, the experimental W sputtering yield due to D⁺ (Y_D/W) can be estimated providing that the target ion flux, the ion impact energy (E_i) and the ion impact angle (θ_i) are known. It has already been established in [5] that electrons have low target temperature (T_e) in ELM conditions and can be repelled by biased Langmuir probes (LP) surfaces to allow reliable ion flux measurements, and also that the maximum E_i has a simple linear dependence with the maximum pedestal T_e (T_e,ped) measured by electron cyclotron emission (ECE). Therefore, experimental estimation of the W sputtering source using ECE and LP measurements seems feasible and has been attempted here.

A high power unseeded H-Mode discharge performed in JET-ILW (#82237) where the W sputtering source has already been estimated using W I spectroscopy [6] has been used for this purpose. This experiment has been chosen for the slow (∼10 Hz) and large Type I ELMs allowing the use of slow W I spectroscopy (∼25 Hz). The divertor configuration used in #82237 features a vertical inner target with a horizontal outer target (OT), see figure 1. The present work has been focused on the use of ECE T_e,ped measurements and LP ion saturation current (J_sat) measurements to estimate the W sputtering source on the horizontal OT in ELM and inter-ELM conditions. This new method provides independent high time resolution (∼10 μs) target measurements which can be compared to W I spectroscopy.

Before estimating the W sputtering source, it is essential to have an idea of E_i,max in this experiment by using ECE pedestal temperature (T_e,ped) measurements (section 2). Then, the experimental W sputtering yields due to D⁺ and Be²⁺ in ELM and inter-ELM conditions can be estimated by calculating the different ion impact angle distributions (section 3).

Figure 1. Left: positions of LP and IR camera line of sight in JET-ILW divertor with the different tile numbers. Right: magnetic equilibrium for #82237 and 84782 at 13 s and position of W I, D₁, spectroscopy and ECE lines of sight in JET-ILW main chamber.
Finally, OT W sputtering sources deduced from LP measurements have been compared to similar estimates made with W I spectroscopy \[6\] (section 4).

2. \(E_i\) estimates during ELMs using ECE measurements

As shown on the example in figure 2 obtained from TRIM [7], the W sputtering yield depends strongly on \(E_i\) for the different possible ion species striking the divertor targets. Previous studies [5] have shown that ELMy electrons have a surprisingly low target \(T_e\). As shown on figure 3, exponential fit of reconstructed ELMy \(I-V\) characteristic from the strike point LP in a Type I ELMy H-mode discharge similar to \#82237 yields \(T_e \sim 20-30\) eV. This means that electrons can be repelled by LP biased surfaces during ELMs to allow ion flux measurements. Indeed, according to the ‘Free-Streaming’ model, it appears that during ELMS, electrons must transfer most of their parallel energy to the ions in order to maintain quasi-neutrality, see \[8-10\]. Therefore, LP ion saturation current \(J_{sat}\) measurements in A.m\(^{-2}\) can be coupled to perpendicular heat flux density \(q_{\perp}\) measurements in W.m\(^{-2}\) from infrared thermography (IR) to derive the sum of \(E_i\) with the electron impact energy \((E_e)\) in eV as follows:

\[
E_i + E_e = \frac{q_{\perp}}{J_{sat} \sin \theta_{\perp}},
\]

with \(\theta_{\perp}\) the field line angle with the OT (~2–3\(^{\circ}\) in JET-ILW). It has been previously verified [5] on several Type I ELMy H-mode discharges in JET-ILW that \(E_i + E_e\) has a simple linear dependence with the \(T_{e,\text{max}}^{\text{ped}}\) such that:

\[
\max(E_i + E_e) \approx \alpha T_{e,\text{max}}^{\text{ped}}
\]

with \(\alpha = 5.23\) according to the ‘Free-Streaming’ model \[8-10\], see figure 4. Since the electron parallel energy is almost entirely transferred to the ions on their way to the target, the model assumes that the perpendicular electron energy \((E_{e,\perp})\) is the only component left in \(E_e\) such that:

\[
E_e = E_{e,\perp} = T_{e}^{\text{ped}}.
\]

Thus, \(E_{i,\text{max}}\) during ELMs is:

\[
E_{i,\text{max}} = (\alpha - 1) T_{e,\text{max}}^{\text{ped}} = 4.23 T_{e,\text{max}}^{\text{ped}}.
\]

Here, the \#82237 JET-ILW Type I ELMy H-mode discharge already used to study the OT W sputtering source with W I spectroscopy \[6\] is considered. According to ECE measurement coherently averaged with the method described in \[11\], \(T_{e,\text{max}}^{\text{ped}}\) is ~0.6 keV here (figure 5(a)), which means that following (4), \(E_{i,\text{max}}\) ~ 2.5–3 keV. Mention has to be made that on ITER \(T_{e,\text{max}}^{\text{ped}}\) ~ 5 keV has been predicted \[12\].
which means that $E_{i,\text{max}} \sim 20\text{ keV}$ can be expected. Therefore, it is worth noting that the range of $E_{i,\text{max}}$ accessible in JET-ILW (2–4 keV according to [5]) allows similar W sputtering yields as those expected in ITER for the species considered in figure 2 since all the curves tend to saturate above $\sim 2–3\text{ keV}$.

In inter-ELM conditions, it is considered, as in [4], that in a JET-ILW low $Z_{\text{eff}}$ plasma ($Z_{\text{eff}} \sim 1.1–1.3$ here) the ion impact energy ($E_{i,\text{inter-ELM}}$), $T_e$, and the target ion temperature ($T_i$) are such that:

$$E_{i,\text{inter-ELM}} \approx 3T_e + 2T_i.$$  

(6)

In #82237, the maximum $T_e$ from LP measurements is not higher than $\sim 30\text{ eV}$ and if it is assumed that $T_i \approx T_e$, $E_{i,\text{inter-ELM}}$ should not exceed $\sim 150\text{ eV}$. For simplification, it is assumed in this work that both species of interest, namely $\text{D}^+$ and $\text{Be}^{2+}$, have the same $E_{i,\text{max}}$ and $E_{i,\text{inter-ELM}}$.

3. Impact angle distribution in ELM and inter-ELM conditions

The W sputtering yield due to $\text{D}^+$ and $\text{Be}^{2+}$ ($Y_{\text{D}/W}$ and $Y_{\text{Be}/W}$ respectively) that we are trying to evaluate here also depend on the ion impact angle ($\theta_i$), as shown on figure 6. Since the variation of $Y_{\text{D}/W}$ and $Y_{\text{Be}/W}$ with $\theta_i$ can be up to an order of magnitude, it is crucial to estimate the distribution of this angle in ELM and inter-ELM conditions for $\text{D}^+$ and $\text{Be}^{2+}$.

In inter-ELM conditions, $Y_{\text{D}/W}$ is neglected and only $Y_{\text{Be}/W}$ is considered. According to kinetic analytical calculations [13] considering a target plasma close to experimental inter-ELM conditions with Maxwellian distribution of energy for ions and electrons, $T_e = T_i = 30\text{ eV}$, $n_e \sim 10^{19}\text{ m}^{-3}$, magnetic field $B = 3\text{ T}$ and $\theta \sim 3^\circ$, the distribution of inter-ELM $\theta_i$ should reach its maximum around $\sim 20^\circ$ for $\text{Be}^{2+}$, see figure 7.

During ELMs, despite $E_{i,\text{max}} \sim 3\text{ keV}$ in average in JET-ILW, the target $T_e$ remains close to the inter-ELMs level. As in the example shown in figure 3, $T_e$ in #82237 should not be above $\sim 30\text{ eV}$ in ELMy conditions. However, the higher number of ionization per $\gamma$, photon required to match LP ion flux measurements in [5], when the recycling coefficient is assumed to be around unity, is an evidence of higher $n_e$ of the order of $\sim 10^{20}\text{ m}^{-3}$ during ELMs. Also, according to the ‘Free-Streaming’ model [8–10], the high energy ELMy ions have a very narrow energy distribution when they reach the target. Kinetic analytical calculations [13] with these conditions and the same $B$ and $\theta_i$ as the inter-ELM case, yield a distribution of $\theta_i$ reaching its maximum around $22^\circ$ for $\text{D}^+$ and $25^\circ$ for $\text{Be}^{2+}$, see figures 8(a) and (b). The small
oscillations in the distribution of $\theta_i$ are due to limitations in the number of test particles used in the kinetic calculations. The level of precision of the calculated distribution is however sufficient to allow estimation of the sputtering yield.

The small difference between ELM and inter-ELM conditions in terms of $\theta_i$ distribution suggests that the latter is more influenced by the ion gyration than the sheath effects. Indeed, if the electric field of the Debye sheath had a strong effect, the $\theta_i$ distribution should be much closer to $90^\circ$. As shown in figure 6, shallow $\theta_i$ around $\sim 20^\circ$ at high $E_{i,max}$ are associated with significant W sputtering yields.

4. Estimation of W impurity sputtering in ELM and inter-ELM conditions

Given the $\theta_i$ distribution obtained previously in inter-ELM, the average $Y_{Be/W}$ should be around $\sim 0.01$ in these conditions, according to figure 6. During ELMs, the average W sputtering yield due to Be$^{2+}$ and D$^+$ should reach $Y_{Be/W} \sim 0.6$ and $Y_{D/W} \sim 0.03$ respectively, considering the ELMy $\theta_i$ distributions previously calculated. Since the Be concentration in the impinging ion flux is expected to be around $\sim 0.5$% in unseeded JET-ILW Type I ELMy H-mode experiments [4], all the required parameters are known to estimate the W sputtering source on the OT by using LP $J_{sat}$ measurements.

The W sputtering flux due to the cumulated effect of D$^+$ and Be$^{2+}$ in ELM and inter-ELM has already been estimated in [6], using W I spectroscopy. However, despite the known $T_e$ dependence of the number of ionizations per emitted photon from W I discussed in [14], the remaining uncertainties related to possible $n_e$ dependence and $T_e$ measurements still leave some room for a significant error. Thus, an uncertainty on the number of ionizations per photon and consequently on the estimated W sputtering source remains. Moreover, the mirror-link system viewing the OT and analyzing the light in three wavelength ranges with Czerny–Turner spectrometers [15] has a time resolution limited to 40 ms which is slow compared to the typical $\sim 1$ ms duration of the Type I ELM events studied here. Typical measurements made during ELMy H-mode discharges with this diagnostic in JET-ILW cumulate light from several ELMs and inter-ELMs and only very slow Type I ELMs like in discharge #82237 can be isolated once or twice over the duration of the experiment ($\sim 5$ s). Thus, these measurements cannot be coherently averaged and ELMs must be very similar all along the discharge in order to consider ELMy W I spectroscopy data representative of a typical ELM.

Since LP $J_{sat}$ measurements are accurate during ELMs and inter-ELMs [5], independent estimation of the W sputtering source based on this signal provides an opportunity for a comparison with the W I spectroscopy technique. This new method involving the LP has the advantage of not relying on any assumptions on atomic physics and benefits from the high time resolution of the $J_{sat}$ signal ($\sim 10 \mu s$) required during ELMs and allowing coherent averaging like in figure 5(b). However, it assumes that relation (4) is true for any Type I ELMy H-mode and that $E_{i,max}$ remains constant at $\sim 3$ keV over the entire OT for a duration of $\Delta t_{ELM} \sim 1$ ms in average (duration of $T^{\text{inel}}_{\text{vel}}$ drop in figure 5(a)) in each ELM event.

The W sputtering flux densities $\Gamma_{W,ELM}$ and $\Gamma_{W,inter-ELM}$ in m$^{-2}$ s$^{-1}$ due to ELM and inter-ELM ion flux respectively have been calculated as follows:

$$\begin{align*}
\Gamma_{W,ELM} \approx J_{sat,ELM} \frac{e}{\pi} \sin(\theta_i) \left[ Y_{D/W} (3 \text{ keV, } 22^\circ) + 0.005 Y_{Be/W} (3 \text{ keV, } 25^\circ) \right] \Delta t_{ELM} f_{ELM},
\end{align*}$$

(7)

$$\begin{align*}
\Gamma_{W,inter-ELM} \approx \frac{0.005 J_{sat,inter-ELM}}{e} \frac{e}{\pi} \sin(\theta_i) \times Y_{Be/W} (150 \text{ eV, } 20^\circ),
\end{align*}$$

(8)

With $J_{sat,ELM}$, $J_{sat,inter-ELM}$ and $f_{ELM}$ the ELMy My $J_{sat}$, the inter-ELM $J_{sat}$ both measured in A.m$^{-2}$ by the LP and the ELM frequency in s$^{-1}$ respectively. Thus, the ELM and inter-ELM experimental perpendicular ion flux density profiles shown on figure 9(a) and obtained from the LP allow the estimated $\Gamma_{W,ELM}$ and $\Gamma_{W,inter-ELM}$ profiles shown on figure 9(b) for the discharge #82237.

Previous $\Gamma_{W,ELM}$ and $\Gamma_{W,inter-ELM}$ profiles deduced from W I spectroscopy [6] are also shown on figure 9(b) for
ELMy W sputtering source in JET-ILW unseeded Type I ELMy H-modes. The order of magnitude of the OT W source in discharge #82237 with an ITER relevant ELM energy drop have shown that $E_{\text{i,max}}$ during ELMs is in the range 2–4 keV for $\text{D}^+$ and has a simple linear dependence on $T_{\text{e, max}}$. Saturation of the ion current measured by the LP during ELMs is possible thanks to the surprisingly low $T_e$ of the order of the inter-ELM conditions which is consistent with the predictions from the ‘Free-Streaming’ model for the description of parallel ELM transport [8–10]. According to the model, electrons have to transfer most of their parallel energy to the ions on their way to the target to maintain the quasi-neutrality of the ELM filaments. The remaining low energy ELMy electrons are therefore easy to repel by the biased LP at the targets, making the ion flux measurement possible during ELMs.

Consequently, providing that the distribution of $\theta_i$ is known, ECE $T_{\text{e, ped}}$ measurements and LP $J_{\text{sat}}$ measurements can be used to estimate the W sputtering source due to $\text{D}^+$ and $\text{Be}^{2+}$ in inter-ELM and ELM conditions. The unseeded Type I ELMy H-mode discharge #82237, where the W sputtering source has already been estimated using W I spectroscopy [6], has been used here for this purpose.

W sputtering flux density profiles obtained from W I spectroscopy and LP measurements differ by less than $\sim 30\%$ in magnitude an confirm the order of magnitude of the W sputtering source with roughly $10^{19}$ atoms per ELM and $\sim 10^{18}$ atoms s$^{-1}$ in inter-ELM in #82237. Since the ELM frequency in this discharge is $\sim 10$ Hz, the ELM W source is dominant by an order of magnitude over the inter-ELM W source.

Comparison of W sputtering flux density profiles due to ELMy $\text{D}^+$ and $\text{Be}^{2+}$ on the OT indicates that $\text{D}^+$ during ELMs is the main contributor to the W sputtering source during ELMs and inter-ELMs is important and can be helped by experimental measurements with improved precision.

Comparison. Both flux density profiles have less than 30% discrepancy in magnitude. OT W sputtering fluence per ELM and OT inter-ELM W sputtering flux from both methods are provided in Table 1. Discrepancies between integrated amounts obtained from both methods of measurements do not exceed a factor $\sim 2$ during ELMs and are below 10% in inter-ELM. The order of magnitude of the OT W source in discharge #82237 with $\sim 10^{19}$ W atoms per ELM and $\sim 10^{18}$ s$^{-1}$ W flux during inter-ELM is confirmed by both techniques. Therefore, given the assumptions and approximations made to get these estimations, this level of agreement is reasonably good.

The comparison of W sputtering flux density profiles due to ELMy $\text{D}^+$ and $\text{Be}^{2+}$ on the OT shown on figure 9(c) indicates that $\text{D}^+$ during ELM is the main contributor to the W source in JET-ILW unseeded Type I ELMy H-modes. Indeed, in these conditions, the $\text{Be}^{2+}$ contribution is lower by an order of magnitude because of the small Be concentration in the impinging ion flux of $\sim 0.5\%$, see [4].

5. Conclusions

Mitigated Type I ELMs expected in ITER for the baseline scenario with 500 MW of fusion power and $Q = 10$, are expected to be the dominant source of W. Very small amounts of W will be tolerated in the plasma core to ensure good performance [2]. Therefore, understanding the physics of the target W source due to sputtering during ELMs and inter-ELMs is important and can be helped by experimental measurements with improved precision.

Previous studies [5] coupling IR and LP measurements in JET-ILW H-mode experiments with ITER relevant ELM energy drop have shown that $E_{\text{i,max}}$ during ELMs is in the range 2–4 keV for $\text{D}^+$ and has a simple linear dependence on $T_{\text{e, max}}$. Saturation of the ion current measured by the LP during ELMs is possible thanks to the surprisingly low $T_e$ of the order of the inter-ELM conditions which is consistent with the predictions from the ‘Free-Streaming’ model for the description of parallel ELM transport [8–10]. According to the model, electrons have to transfer most of their parallel energy to the ions on their way to the target to maintain the quasi-neutrality of the ELM filaments. The remaining low energy ELMy electrons are therefore easy to repel by the biased LP at the targets, making the ion flux measurement possible during ELMs.

Consequently, providing that the distribution of $\theta_i$ is known, ECE $T_{\text{e, ped}}$ measurements and LP $J_{\text{sat}}$ measurements can be used to estimate the W sputtering source due to $\text{D}^+$ and $\text{Be}^{2+}$ in inter-ELM and ELM conditions. The unseeded Type I ELMy H-mode discharge #82237, where the W sputtering source has already been estimated using W I spectroscopy [6], has been used here for this purpose.

W sputtering flux density profiles obtained from W I spectroscopy and LP measurements differ by less than $\sim 30\%$ in magnitude an confirm the order of magnitude of the W sputtering source with roughly $10^{18}$ atoms per ELM and $\sim 10^{19}$ atoms.s$^{-1}$ in inter-ELM in #82237. Since the ELM frequency in this discharge is $\sim 10$ Hz, the ELM W source is dominant by an order of magnitude over the inter-ELM W source.

Figure 9. (a) OT perpendicular ion flux density profile from LP, (b) OT total W sputtering flux density profile from WI spectroscopy (dashed curves) and LP (plain curves) due to ELM (red curves) and inter-ELM (blue curves) and (c) contribution from $\text{D}^+$ (plain curve) and $\text{Be}^{2+}$ (dashed curve) to OT W sputtering flux density profile.
ELMs is the main contributor to the W source. The Be$^{2+}$ contribution is lower by an order of magnitude because of the small Be concentration in the impinging ion flux of $\sim 0.5\%$ in JET-ILW unseeded Type I ELMy H-modes, see [4].

Given the uncertainty on the number of ionizations per photon in W I spectroscopy and the approximation that $E_{\text{ion max}}$ remains constant at $\sim 3\, \text{keV}$ over the entire OT during each ELM event, OT W sputtering source estimates from both methods are in reasonably good agreement.

The very high time resolution ($\sim 10\, \mu\text{s}$) of the LP $J_{\text{sat}}$ measurements is a strong advantage which should allow the use of this new technique to estimate the W sputtering source in other conditions where ELMs are usually too fast for W I spectroscopy like seeded H-mode discharges or ELM pacing experiments.
