(Received 5 March 1991)

A Monte Carlo investigation of the linear and nonlinear relaxation of a one-dimensional bonded fluid is presented. The simulation shows that the model possesses many of the qualitative properties of the glass-forming liquids. The linear response function exhibits nonexponential relaxation, and it can be fitted quite accurately with the Kohlrausch-Williams-Watts expression. The average relaxation time has a non-Arrhenius temperature dependence. Simulations of temperature jumps have also been performed, and we find that in some cases the relaxation of the model is not monotonic.

I. INTRODUCTION

Glass-forming liquids display a quite characteristic relaxation behavior. Although the quantitative aspects seem to depend strongly on the details of the specific material under consideration, the general picture that appears from the experimental results corresponds to some kind of universal behavior. In fact, several general phenomenological theories have been proposed that have proved to be very successful in describing a great variety of viscous fluids and glasses.1–3

From a physical point of view, little is known about the relevant processes that control relaxation in glass-forming liquids. A large number of models showing at least some of the observed experimental properties have been analyzed, but the physical mechanisms invoked to account for the glassy behavior are very different, and even contradictory.4–5 A fundamental question in this respect is whether it is meaningful to talk about glasses, in general, or one has to consider each of them at an (almost) individual level.

Lacking a general well-established theory, it seems worth while to keep looking for specific models, as simple as possible, that mimic the dynamical properties of real supercooled liquids and glasses. In particular, we believe that it is interesting to study models having the following two features. First, they must have well defined and consistent thermodynamic and kinetic properties. Second, they must be simple enough to allow a rigorous investigation. A primary goal should be to identify the conditions required for a model in order to be able to describe glassy dynamical properties.

In this paper we use Monte Carlo simulation to discuss the linear and nonlinear relaxation properties of a one-dimensional bonded fluid. It is a lattice model whose thermodynamic properties were studied by Bell.6 Very recently,7 the model was also given kinetic properties by defining a master equation with transition probabilities that are consistent with the Hamiltonian. Previous Monte Carlo simulation has shown that the model presents, under continuous cooling, a phenomenon that is similar to the laboratory glass transition in real glasses.

In Sec. II, the one-dimensional bonded fluid is defined. Since it has already been discussed elsewhere,6,7 only a brief description will be given. The same also applies to the technical details of the Monte Carlo simulation to be discussed at the beginning of Sec. III. The simulation is used to analyze the equilibrium time correlation function characterizing the response in energy to an infinitesimal perturbation in the limit of a very long wavelength. In Sec. IV, the nonequilibrium relaxation following a finite temperature jump is studied. Section V contains some comments and discussions.

II. BOND-FLUID MODEL

We consider a collection of $M$ particles in a one-dimensional lattice of $N$ sites. The interaction energy between two nearest-neighbor particles is $-\varepsilon$. Two particles separated by a single empty site may establish a bond of energy $-(\varepsilon + \omega)$ between them. In this case it is convenient to think of the empty site as being occupied by a bond. No other interactions are possible in the system.

To specify a configuration, the position of the particles on the lattice and also the existing bonds must be given. The energy of a given configuration $\mathbf{x}$ of the lattice is, assuming periodic boundary conditions,

$$E(\mathbf{x}) = -(M-Z)\varepsilon - B\omega,$$

where $B$ is the number of bonds and $2Z$ is the number of particle-hole contacts in the configuration. A hole is an empty site that is not being occupied by a bond. Since we are dealing with a one-dimensional model with short-range interactions, the system will not present thermodynamic phase transition.

The equilibrium properties of the system are easily derived by constructing the isothermal-isobaric partition function,6,7 or by using the transfer-matrix method.6 Their expressions will not be given here. The dynamics of the model is defined by means of a master equation for the probability distribution, $P(\mathbf{x},t)$, of configuration $\mathbf{x}$ at time $t$,

$$\frac{\partial}{\partial t}P(\mathbf{x},t) = \sum_{\mathbf{x}'} [W(\mathbf{x}' \to \mathbf{x})P(\mathbf{x}',t)$$

$$-W(\mathbf{x} \to \mathbf{x}')P(\mathbf{x},t)].$$

The transition rates $W(\mathbf{x} \to \mathbf{x}')$ from configuration $\mathbf{x}$ to
configuration \( \mathbf{x}' \) are defined in the following way. A particle can jump to a next empty site if and only if it is not bonded to another particle. Bonds between particles can be destroyed, and a bond can also be created between two particles separated by a single empty site. For the allowed transitions, the transition rate is given by

\[
W(\mathbf{x} \rightarrow \mathbf{x}') = \frac{1}{2\tau_0} \left[ 1 - \tanh \frac{\Delta E}{2k_B T} \right],
\]

where \( \tau_0 \) is a natural attempt frequency, \( k_B \) is the Boltzmann constant, \( T \) the temperature, and \( \Delta E = E(\mathbf{x}') - E(\mathbf{x}) \). The above definition of the transition probabilities guarantees that the Markov process is irreducible and, therefore, any initial distribution \( P(\mathbf{x},0) \) will approach in time the canonical form

\[
P_{eq}(\mathbf{x}) \sim \exp \left( \frac{-E(\mathbf{x})}{k_B T} \right).
\]

As the temperature is lowered, the number of holes and particle-particle contacts decreases. To relax a perturbation, the system needs to destroy an increasing number of bonds before a hole finds a couple of particles, it jumps between them, and afterwards creates a new bond. It follows that we can expect our system to show a temperature-dependent activation energy. For comparison purposes it must be realized that the dynamics of the bonded-fluid model does not involve any kind of external disorder or any geometrical constraints restricting the number of allowed transitions.

**III. LINEAR RESPONSE**

The response in energy of the system to an infinitesimal homogeneous perturbation is characterized by the correlation function

\[
\phi(t) = \frac{\langle E(t)E(0) \rangle - \langle E \rangle^2}{\langle E^2 \rangle - \langle E \rangle^2},
\]

where the angular brackets denote the equilibrium average at the given temperature. The function \( \phi(t) \) is defined such that \( \phi(0) = 1 \).

We have investigated the behavior of the response function \( \phi(t) \) of our model through Monte Carlo simulations with periodic boundary conditions. The details of the algorithm have been presented in Ref. 7. We started the simulations with the system in equilibrium at the temperature \( T = 0^\circ \). For a system with number of sites twice the number of particles, there is a unique equilibrium configuration corresponding to such temperature: a structure in which every two particles are separated by a hole, without bonds between particles. From this state of zero energy, an instantaneous quench to a given temperature was carried out. Afterwards, the system was allowed to relax to equilibrium before we start recording the energy \( E(t) \).

The lattice used in the simulation had 200 sites and 100 particles, and the interaction energies were given values \( e = 200 \) and \( \omega = 500 \), in arbitrary units. For all the ranges of temperatures investigated, \( 200 \leq k_B T \leq 700 \), the equilibrium correlation length, estimated by using the transfer-matrix method, is much smaller than the length of the system. Anyway, we have checked that the results did not change significantly as the size of the system is increased. As an example, Fig. 1 shows the results obtained for \( \phi(t) \) on the systems of sizes \( N = 200, 400, \) and \( 1000 \), at \( k_B T = 300 \). Due to computer time limitations, the number of independent runs performed was smaller the larger the system was. For \( N = 200 \), the results were averaged over 500 runs, for \( N = 400 \) the number of runs was 50, and 40 for \( N = 1000 \). From the comparison of the three curves in Fig. 1 it follows that the best compromise choice is \( N = 200 \), because it gives enough accuracy and allows one to decrease the fluctuations by considering a larger number of independent runs. All the results to be presented in the following correspond to a system with 100 particles, averaged over 500 trajectories.

For each of the studied temperatures, the correlation function \( \phi(t) \) was fitted to the Kohlrausch-Williams-Watts (KWW) function:

\[
\frac{1}{t^{\gamma}} = \exp \left( \frac{-t}{\tau_\infty} \right),
\]

**FIG. 1.** Energy correlation function at \( k_B T = 300 \) for three different sizes of the system. The curves are the average over 500 independent runs for \( N = 200 \), over 50 for \( N = 400 \), and over 40 for \( N = 1000 \).

**FIG. 2.** KWW fit of the linear relaxation function for \( k_B T = 280 \). The solid line corresponds to values of the parameters \( \tau_\infty = 42.87 \) and \( \gamma = 0.368 \).
\[ \phi(t) = \exp \left( - \frac{t}{\tau_w} \right)^\gamma \]  

(3.2)

with \( \tau_w \) and \( \gamma \) being adjustable parameters. Only the values in the interval \( 0.03 \leq \phi(t) \leq 0.5 \) were used in the fitting of the curves. This region accounts for most of the area under \( \phi(t) \). In Fig. 2 we have plotted \( \ln(-\ln\phi) \) versus \( \ln t \) for \( k_B T = 280 \). The solid line is the KWW fit with parameters \( \tau_w = 42.87 \) and \( \gamma = 0.368 \). In general, the agreement is better the lower the temperature, as can be seen from Figs. 3 and 4, where the correlation functions at \( k_B T = 280 \) and 500 are shown. Also notice that systematic deviations from the KWW behavior are observed in the short-time region.

The values of \( \tau_w \) and \( \gamma \) obtained from the fittings are given in Table I. From the values of \( \gamma \) it follows that the correlation function has a highly nonexponential decay, showing a broad relaxation spectrum. Besides, the temperature dependence of \( \gamma \) implies the lack of thermoreological simplicity of the model,\(^2\) i.e., the temperature dependence of \( \phi \) cannot be described by means of a single time scaling. Nevertheless, it must be noticed that, for not too large temperature intervals, the model could give the appearance of thermoreological simplicity.

Although there is a clear tendency of \( \gamma \) to decrease as the temperature decreases, the dependence of \( \gamma \) on the temperature does not appear to be monotonous in the low-temperature region. In this respect our results differ from those obtained by Fredrickson for facilitated Ising models,\(^4,9\) and agree with the behavior found by Stillinger and Weber for tiling models.\(^10\)

We have also investigated the temperature dependence of the average relaxation time defined by

\[ \bar{\tau} = \int_0^\infty dt \phi(t) . \]  

(3.3)

To evaluate this expression we have used the KWW expression with the values of the parameters obtained in the previous fit. The results are also listed in Table I.

An expression that is often used to fit the experimental data for the temperature dependence of the average relaxation time in glasses is the so-called Vogel-Tamman-Fulcher (VTF) form

\[ \bar{\tau} = \exp \left( \frac{E_0}{T - T_0} \right) , \]  

(3.4)

where \( E_0 \) and \( T_0 \) are adjustable parameters. Figure 5 shows a fit of Eq. (3.4) to our data. The parameters are \( k_B T_0 = 74 \) and \( k_B E_0 = 1098 \). The curvature of the plot clearly indicates that the kinetics of the model does not obey the Arrhenius equation. More precisely, the apparent activation energy

\[ E_a = \frac{d}{d(1/k_B T)} \ln \bar{\tau} \]  

(3.5)

is seen to increase as the temperature decreases. This is also a characteristic of many glass-forming liquids.\(^11\)

It must be noticed that the value of \( T_0 \) obtained from the fit of Eq. (3.4) is well below the range of temperatures of the Monte Carlo simulation data. This prevents us from extrapolating the validity of Eq. (3.4) to the neighborhood of \( T_0 \), and to conclude that the model presents a kinetic singularity at \( k_B T = 74 \). In fact, the results to be discussed in the next section show that there is no such singularity. Therefore, the VTF expression must only be

considered as a useful expression to describe the behavior of the average relaxation time in the range of temperatures we have studied. The temperature $T_0$ can, at the most, be associated with a change in the qualitative behavior of $\tau$.

It is also interesting to attempt to fit our data to the expression proposed by Adam and Gibbs\textsuperscript{12}

$$\tau = \exp \left( \frac{E_1}{TS_c} \right),$$

where $E_1$ is a temperature-independent parameter and $S_c$ is the configurational entropy. The latter can be identified in our model with the total equilibrium entropy that is easily computed.\textsuperscript{6,7} In Fig. 6 the logarithm of the average relaxation time is plotted versus $(TS_c)^{-1}$. The apparent curvature of the plot indicates that our model significantly deviates from the Adam-Gibbs expression. More will be said about this point in the last section.

### IV. RESPONSE TO INSTANTANEOUS QUENCHES

We have carried out a series of experiments to study the relaxation of the system after an instantaneous quench from $T=0$ to a low (positive) temperature. It must be kept in mind that, in this kind of model, negative temperatures correspond to states with a larger energy.

The relaxation of the energy of the model can be characterized by the nonlinear response function

$$\psi(t) = \frac{\langle E(t) \rangle - \langle E \rangle}{\langle E(0) \rangle - \langle E \rangle} = 1 - \frac{\langle E(t) \rangle}{\langle E \rangle}.$$  \hspace{1cm} (4.1)

Here $\langle E(t) \rangle$ is the nonequilibrium average energy at time $t$, and $\langle E \rangle$ the equilibrium average energy corresponding to the temperature after the quench.

The results we present in this section correspond again to a lattice of 200 sites with 100 particles, and they have been averaged over 1000 independent trajectories. For some of the lowest temperatures considered, we have checked that the results are not significantly altered when the number of particles is increased to 1000 (2000 sites).

From Eq. (4.1) it follows that $\psi(0) = 1$, and that the relaxation of the system towards equilibrium implies $\psi(\infty) = 0$. At all the temperatures investigated ($50 \leq k_BT \leq 1000$), it was observed that $\psi(t)$ decays to zero for large enough times. This is important with regard to the discussion in the previous section. If there were a dynamical transition at $k_BT_0 \approx 74$, one should expect that the system would not be able to equilibrate below that temperature. Since that was not the case, we conclude that the singularity present in Eq. (3.4) is artificial and, therefore, that expression does not apply when one approaches $T_0$ from above.

Nevertheless, although the system always goes to equilibrium, important qualitative differences appear in the relaxation. For $K_BT > 150$ the relaxation is not monotonous. There is a fast initial decay of the average energy that is overshot below its equilibrium value. An example is shown in Fig. 7 that corresponds to $k_BT = 1000$. The final relaxation takes place through negative values of $\psi$.

This behavior can be easily explained in terms of the
elementary processes taking place in the system. Because of the initial configuration we have chosen, there is a great tendency to create bonds, as those are the most favorable transitions from the energetic point of view. In this way, the system builds up a number of bonds larger than the equilibrium one. This has been verified by following the evolution of the configurations in the simulation.

At lower temperatures \((k_B T < 150)\), the relaxation is monotonous, but highly nonexponential. There is an almost instantaneous decay of the response function to values of the order of 0.2. Afterwards, the relaxation is much slower. At the lowest temperatures studied, \(k_B T = 50\), runs of approximately \(3 \times 10^7\) MCS were required for \(\psi(t)\) to decay to values of the order of 0.05.

Following a similar study by Fredrickson and Brawer\(^{13}\) for a facilitated Ising model, we have fitted the relaxation data at low temperatures to a KWW function

\[
\psi(t) = \exp \left[ -\left( \frac{t}{\tau_q} \right)^{\gamma'} \right].
\]

(4.2)

Of course, the meaning of these fits is quite different from the ones carried out for the linear relaxation function. Here, Eq. (4.2) must be understood only as a convenient way of analyzing the results. In obtaining these fits, all the data points for \(\psi(t)\) were used. The fits turn out to be reasonably good beyond the initial fast decay. In Fig. 8 we have plotted the simulation data and the fit for the lowest studied temperature, \(k_B T = 50\). The values of the parameters obtained are \(\gamma' = 0.16\) and \(\tau_q = 9.0 \times 10^3\), showing that the relaxation cannot be described by a single exponential.

In Table II we present the values of \(\gamma'\) and \(\tau_q\) obtained for all the low temperatures \((k_B T \leq 120)\) investigated. Also, the average relaxation times, defined by the area under \(\psi(t)\), are given. Comparison of Tables I and II shows that the exponents \(\gamma'\) are smaller than the \(\gamma\) ones, while the relaxation times \(\tau_q\) are much larger than the \(\tau\) ones. Although it can be associated to the fact that the temperatures are smaller in Table II than in Table I, the different physical meaning of both sets of relaxation times must be noticed.

The exponent \(\gamma'\) seems to depend very weakly on the temperature, although it appears to decrease slightly as the temperature is lowered. On the other hand, \(\tau_q\) and \(\tau_q\) are strongly temperature dependent, and show a fast increase as the temperature decreases. Figure 9 is an Arrhenius plot of the average relaxation times. Although the data points cannot be accurately fitted by a straight line, a tendency towards Arrhenius behavior is observed for temperatures below \(k_B T \approx 90\). This reminds the behavior of some fragile fluids, for which a return to an Arrhenius temperature dependence of the relaxation time has been observed, when approaching the laboratory glass transition temperatures from above.

V. DISCUSSION

The results presented in this paper and in Ref. 7 show that the one-dimensional bonded-fluid model presents many of the dynamical properties of real glass-forming liquids. It has been found that the linear relaxation function for the model has a highly nonexponential decay that can be fitted reasonably well with the KWW expression. The values of the KWW exponent are of the same order as in real glasses, and they show a tendency to decrease as

![FIG. 8. KWW fit of the nonlinear response function following an instantaneous quench from \(k_B T = 0^-\) to 50. The values of the fitting parameters are given in Table II.](image)

![FIG. 9. Arrhenius plot of the average relaxation times after an instantaneous quench from \(k_B T = 0^-\).](image)
the temperature is lowered. The average relaxation times increase very fast when one approaches the low-temperature region, and their behavior can be accurately described by the empirical VTF law in all the ranges of temperatures we have studied.

A point that deserves some comments is the validity of the Adam-Gibbs relation, Eq. (3.6), for this kind of lattice model. Once one identifies the structural entropy with the equilibrium entropy of the system, Eq. (3.6) establishes a relation between an equilibrium property and a pure dynamical property, the average relaxation time. Nevertheless, the statics of the model does not determine its dynamics when the latter is formulated in terms of a master equation. There are many different ways of defining a set of transition probabilities that are compatible with a given equilibrium distribution, even if detailed balance is required. Of course, the situation is not the same when a complete and consistent Hamiltonian description of the system is used.

From the above discussion it follows that, unless some additional condition is introduced in the definition of the transition rates, it is a matter of chance whether the model will obey the Adam-Gibbs relation or not. Therefore, we believe that nothing physically deep is behind the fact that the facilitated Ising models accurately obey the Adam-Gibbs relation, whereas the tiling models and the bonded-fluid model show a clear departure therefrom.

An important feature of our model is the nonmonotonic relaxation after some instantaneous jumps of temperature. At this moment we do not know whether this is only an artificial property of our model or it is related to some actual behavior of real glasses.

We have now several models that successfully describe many of the characteristics of real glass-forming liquids. These models allow quite efficient computer simulations and, therefore, can be used to test approximate methods. Besides, they prove that very different mechanisms are able to produce glassy behavior and, therefore, one of the key questions remains. Can we really talk about a general kind of systems named glasses?
