# Mediation Analysis in Partial Least Squares Path Modeling: Helping Researchers Discuss More Sophisticated Models

## 1. Introduction

PLS is a variance-based structural equation modeling technique that has become very popular in management and social sciences in recent years. Current discussions about PLS emphasize its capability to model both composites and factors ([Henseler et al., 2016](#)) and its prediction orientation ([Shmueli et al., in press](#)). In addition to these reasons, PLS is a useful tool for testing hypotheses especially in complex path models in an explorative manner ([Chin, 2010](#), [Wold, 1980](#)). Nevertheless, with complex path models, it is much easier to overlook the occurrence of effects that do not directly manifest their influence (cf. [Hair et al., 2012](#), [Nitzl, in press](#)). In a naïve manner, researchers focus only on direct relationships and ignore mediating effects completely. This focus can heavily bias the interpretation of the results when a variable has no direct effect because its effect is mediated by another variable. In the worst case, researchers assume that a variable is not relevant for answering their research question at all.

Despite an increasing use and awareness of mediation effects, studies in PLS often do not consider mediating effects explicitly in their hypotheses and also do not analyze mediating effects in their path models ([Hair et al., 2013](#)). Only a third of the PLS studies published in top-tier marketing and management accounting journals and only 20 percent of the PLS-SEM studies published in the *MIS Quarterly* journal conducted an explicit mediator analysis ([Hair et al., 2012](#), [Ringle et al., 2012](#), [Nitzl, in press](#)). In their review of five leading organization studies journals, [Wood et al. \(2008b\)](#) reported that 92 of 102 studies using mainly covariance-based structural equation

1  
2  
3 modeling (CB-SEM) tested mediating effects. Their review illustrates the prevalence of mediation  
4  
5 analysis for structural equation modeling.  
6  
7  
8  
9

10  
11  
12 To understand the relevance of testing mediating effects in a PLS-SEM, it is first necessary to  
13  
14 understand what mediating effects are. The core of mediation analysis is that it assumes a sequence  
15  
16 of relationships in which an antecedent variable affects a mediating variable, which then affects a  
17  
18 dependent variable. In this way, “mediation is one way that a researcher can explain the process or  
19  
20 mechanism by which one variable affects another” ([MacKinnon et al., 2007](#)). Understanding  
21  
22 mediation questions are important for researchers in several ways: (1) they are the foundations of  
23  
24 many management topics that can, for example, explain how certain process factors improve or  
25  
26 hinder the influence of success drivers (e.g., [Cepeda and Vera, 2007](#), [Castro and Roldán, 2013](#));  
27  
28 (2) there is a methodological challenge, that is to say, the inclusion of a third variable that plays an  
29  
30 intermediate role in the relationship between two variables in a model.  
31  
32  
33  
34  
35  
36  
37  
38

39 Over the past few years, these technical challenges have already constituted a vibrant research topic  
40  
41 in the quantitative methods domain such as multiple regression analysis and CB-SEM ([Hayes and](#)  
42  
43 [Scharkow, 2013](#), [Preacher and Hayes, 2008](#), [Rucker et al., 2011](#)). For example, [Zhao et al. \(2010\)](#)  
44  
45 demonstrated the misapplication of Baron and Kenny’s procedure in the multiple regression  
46  
47 analysis field ([Baron and Kenny, 1986](#)). CB-SEM researchers often consider the latest findings  
48  
49 when testing mediation such as testing the indirect effects with the help of bootstrapping (e.g.,  
50  
51 [Iacobucci et al., 2007](#), [Hair et al., 2010](#)), whereas a number of PLS researchers still fail to do so  
52  
53 (some current examples are [Chi et al. \(2015\)](#), [Jiang and Zhao \(2014\)](#), [Yu et al. \(2015\)](#)). [Nitzl \(in](#)  
54  
55 [press](#)) illustrate that almost all PLS-SEM in management accounting research uses more or less the  
56  
57  
58  
59  
60

1  
2  
3 outdated causal step approach by Baron and Kenny (1986). This finding is somewhat surprising  
4  
5 because state-of-the-art applications for testing the significance of a mediator are very suitable for  
6  
7 PLS as well.  
8  
9

10  
11  
12 Even though initial and early updated proposals have been made for testing mediating effects in  
13  
14 studies that applied PLS (cf. [Chin, 2010](#), [Sosik et al., 2009](#), [Streukens et al., 2010](#)), they have not  
15  
16 found their way to broader application so far. One reason for this seems to be the lack of established  
17  
18 knowledge on procedures as well as consolidated guidelines on conducting state-of-the-art  
19  
20 mediation analysis. Hence, our contribution is a reaction to the call of [Henseler et al. \(2016\)](#) for  
21  
22 new guidelines related to all aspects of PLS for serving as a suitable technique.  
23  
24  
25  
26  
27  
28

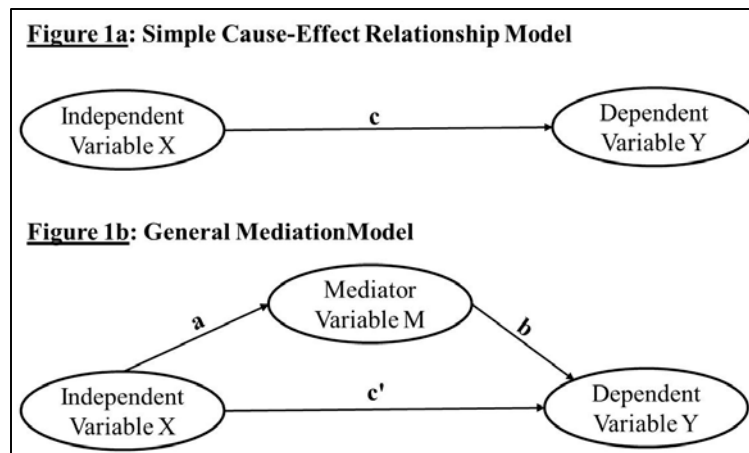

29 The objective of our contribution is to bridge this void by providing researchers with the necessary  
30  
31 information to implement mediation models in PLS. We offer complete guidelines on how to  
32  
33 conduct mediation analysis using PLS. Inspired by [Zhao et al. \(2010\)](#)'s paper, we use modern  
34  
35 literature on mediation in quantitative methods (i.e., regression and CB-SEM) and transfer it to the  
36  
37 PLS domain. We provide a typology of mediation and a decision tree as guidelines. We also factor  
38  
39 the characteristics of PLS into consideration.  
40  
41  
42  
43  
44  
45

46 Our article is structured as follows. After we define mediating effects, we describe Baron and  
47  
48 Kenny's ([1986](#)) approach for testing mediation in Section 2. Their approach is our starting point  
49  
50 because it is well known and researchers in PLS often pursue strategies that are in line with it. We  
51  
52 discuss certain drawbacks to Baron and Kenny's ([1986](#)) approach, including the separate  
53  
54 examination of direct, indirect, and total effects. Based on this, in Section 3, we provide a decision  
55  
56 tree and classification of approaches suitable for PLS. In Section 4, we discuss additional aspects  
57  
58  
59  
60

1  
2  
3 of the assessments of mediation in the context of PLS. Thereafter, we describe an important  
4 extension testing multiple mediations. Finally, in Section 6, we summarize our findings.

7  
8  
9  
10

## 11 12 13 **2. The Mediating effect and Baron and Kenny's Procedure and Beyond**

14  
15 The core characteristic of a mediating effect (i.e., indirect effect or mediation) is that it involves a  
16 third variable that plays an intermediate role in the relationship between the independent and  
17 dependent variables. Technically speaking, the effect of the independent variable X on the  
18 dependent variable Y is mediated by a third variable, M, called the mediating variable or mediator  
19 (see Figure 1). Figure 1a shows the total effect  $c$  of the causal relationship between variables X and  
20 Y, and Figure 1b shows a mediated effect in which X exerts an indirect effect  $a \times b$  through M on  
21 Y. Thus, when we formulate mediation hypotheses, we focus on how an independent variable (X)  
22 affects a dependent variable (Y) by an intervening variables (M) ([Baron and Kenny, 1986](#)). The  
23 researcher's aim in mediation analysis is chiefly explanation because the main subject of mediation  
24 is to understand the development of processes ([Henseler et al., 2016](#), [Iacobucci et al., 2007](#)).  
25 However, mediation analysis could also play an important role in prediction ([Shmueli et al., in](#)  
26 [press](#)).

**Figure 1:** Simple Cause-Effect Relationship and General Mediation Model

Most scholars followed a procedure similar to that proposed by [Baron and Kenny \(1986\)](#) for multiple regression analysis in PLS. [Preacher and Hayes \(2008\)](#) summarized this approach as follows: “Variable M is a mediator if X significantly accounts for variability in M, X significantly accounts for variability in Y, M significantly accounts for variability in Y when controlling for X, and the effect of X on Y decreases substantially when M is entered simultaneously with X as a predictor of Y.” Baron and Kenny’s (1986) method assumes that testing the difference between  $c$  and  $c'$  is equal to testing whether the strength of the indirect path  $a \times b$  is significantly different from zero, and this is the main criterion for determining mediation ([Iacobucci et al., 2007](#))

However, in recent years, Baron and Kenny’s (1986) causal-step approach for determining mediating effects has been challenged considerably by authors such as [Shrout and Bolger \(2002\)](#), [Preacher and Hayes \(2004\)](#), [Preacher and Hayes \(2008\)](#), and [Zhao et al. \(2010\)](#), who call for a reconsideration of Baron and Kenny’s (1986) method and suggest applying new procedures. For example, [Shrout and Bolger \(2002\)](#) argued that Baron and Kenny’s (1986) first condition, that X needs to show a significant effect  $c$  on Y in the first step means an effect  $c$  should exist at all and

1  
2  
3 that something can be mediated, should not be a requirement for the existence of mediation.  
4  
5 Initially, it seems unnecessary to further investigate whether there is a mediated effect if there is  
6  
7 no effect  $c$ ; however, this argument holds only when complementary mediation occurs in a research  
8  
9 model ([Zhao et al., 2010](#)), which is the case only when path  $c$  has the same effect direction (i.e.,  
10  
11 positive or negative) as that of the indirect path  $a \times b$ . In the case of competitive mediation, where  
12  
13 the effect of the indirect path  $a \times b$  differs from that of path  $c$ , this requirement no longer holds. In  
14  
15 complex structural equation models, this can become critical because different types of mediation  
16  
17 can occur in the same model at once. In such a case, it is possible that the direct effect  $c$  is not  
18  
19 significant even if mediation exists and is therefore misleading as a precondition for mediation  
20  
21 analysis. Furthermore, calculating the direct effect  $c$  is also problematic because it would require  
22  
23 estimating the path coefficient of the model in a stepwise approach in different estimated path  
24  
25 models in PLS. In the simplest form of mediation, this would mean first calculating a model with  
26  
27 only the total effect  $c$  such as that shown in Figure 1a. Thereafter, the mediation variable has to be  
28  
29 included in the structural equation model such as the one shown in Figure 1b (for a practical  
30  
31 example, cf. [Nitzl and Hirsch \(in press\)](#)). Similar to other methods for analyzing mediating effects,  
32  
33 in PLS, the estimation of the loadings or weights of the measurements of latent variables could  
34  
35 depend on the variables that are considered in a research model. Because of these measurement  
36  
37 differences that could occur in the casual step approach when including a new variable, this  
38  
39 workaround could cause biases in the estimation of the path coefficients. Hence, this possible path  
40  
41 difference can bias the evolution of mediating effects. However, in contrast to regression analysis,  
42  
43 this step-wise approach is not necessary as PLS is able to test mediating effects in a single model  
44  
45 at once.  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 Based on these shortcomings and the growing array of alternative approaches, state-of-the-art  
4 guidelines have to consider the following points for testing mediating effects in PLS ([Preacher and](#)  
5  
6 [Hayes, 2008](#), [Shrout and Bolger, 2002](#), [Zhao et al., 2010](#)):  
7  
8  
9

- 10  
11  
12 • First, testing the indirect effect  $a \times b$  provides researchers with all information for testing  
13 mediation.  
14  
15
- 16  
17 • Second, the strength of the indirect effect  $a \times b$  should determine the size of the mediation.  
18  
19
- 20 • Third, a bootstrap test should be used to test the significance of the indirect effect  $a \times b$ .  
21  
22  
23

24  
25 In the following section, we discuss these elements in more detail and how they should be used to  
26 detect and define mediating effects in PLS.  
27  
28  
29  
30  
31  
32  
33

### 34 **3. Advanced Procedure for Mediation Analysis in PLS**

35  
36 As shown, PLS researchers have to start by testing the indirect effect  $a \times b$  when analyzing  
37 mediating effects. The indirect effect can also be formulated as the difference between the total  
38 and direct effect:  
39  
40  
41  
42  
43  
44  
45

$$46 \quad (1) \quad \textit{indirect effect } (a \times b) = \textit{total effect } (c) - \textit{direct effect } (c')$$

47  
48  
49  
50  
51

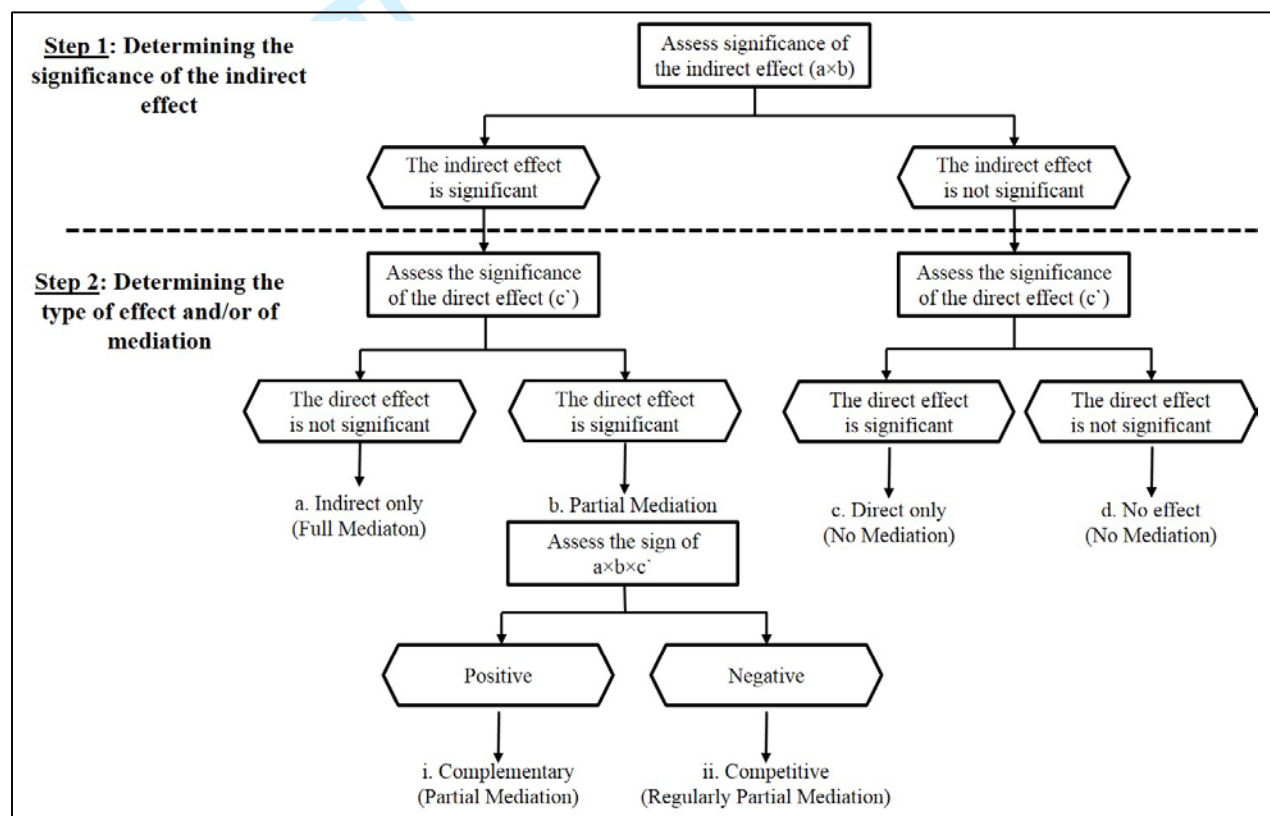

52 In Formula 1,  $c$  represents the total effect and not the effect to be mediated. Consequently,  $c$  does  
53 not constrain the size of  $a$  and  $b$  or their product ([Hayes, 2009](#)); this indicates that it is no longer  
54 necessary to test a separate model to obtain the total effect  $c$  in a PLS model (Figure 1a). Although,  
55  
56  
57  
58  
59  
60

researchers should regularly include the direct effect  $c'$  in their PLS to control and determine the type of mediating effect.

Figure 2 shows a decision tree that can be used to determine the type of mediation analysis. It includes two steps that reflect the abovementioned recommendations for state-of-the-art mediation analysis.

In the following, we describe these two steps in detail.

**Figure 2:** Mediator analysis procedure in PLS (cf. Zhao et al., 2010)

### *Step 1: Determining the significance of indirect effects*

In Step 1, the indirect effect is tested for significance. In the simplest form of mediation, the indirect effect is the product  $a \times b$  of the two paths (1) from the source construct  $X$  to the mediator construct  $M$  (path  $a$ ) and (2) from the mediator construct  $M$  to the target construct  $Y$  (path  $b$ ). PLS researchers

1  
2  
3 have often applied the parametric [Sobel \(1982\)](#) test for testing indirect effects (e.g., [Helm et al.,](#)  
4 [2010](#), [Nitzl and Hirsch, in press](#)). Preacher and Hayes ([2004](#), [2008](#)) show that the Sobel test is not  
5  
6 appropriate for analyzing indirect effects because the parametric assumptions (i.e., normality) of  
7  
8 paths  $a$  and  $b$  do not hold for the product term of the two paths (i.e.,  $a \times b$ ) if one assumes that  $a$   
9  
10 and  $b$  are normal distributed. This bias is especially relevant for small sample sizes, which is often  
11  
12 the case in PLS ([Shrout and Bolger, 2002](#)). Alternatively, researchers should apply bootstrap  
13  
14 routines to test the significance of the indirect effect  $a \times b$ .  
15  
16  
17  
18  
19

20  
21  
22 The bootstrapping procedure is a non-parametric inferential technique that randomly draws several  
23  
24 subsamples (e.g., 5,000) with replacement from the original dataset. Bootstrapping a data sample  
25  
26 of an indirect effect is necessary to obtain information about the population distribution, which is  
27  
28 then the basis for hypotheses testing. Hence, bootstrapping routines do not require assumptions  
29  
30 about the shape of the variable distribution ([cf. Chin, 2010](#)). In the first step in a PLS, the data for  
31  
32 each item of the measurement are bootstrapped. In the next step, the bootstrapped results are  
33  
34 separately used to estimate the underlying PLS path model. The different model estimations  
35  
36 provide the distribution of the path coefficients for the inner path model.  
37  
38  
39  
40  
41  
42

43  
44 The bootstrap routines in the PLS software often provide bootstrap results for at least direct effects  
45  
46 (e.g., path  $a$  and path  $b$ ). However, for a more detailed analysis of mediation, particularly in more  
47  
48 complex model structures (e.g., multiple mediators), it is often necessary to compute the  
49  
50 bootstrapping results for the combination of  $a \times b$  of a certain indirect effect with the help of a  
51  
52 spreadsheet application, such as Microsoft Excel or CALC in OpenOffice. For each bootstrapping  
53  
54 subsample, the results of path  $a$  must be multiplied by path  $b$  to create the product term  $a \times b$  of  
55  
56 the indirect effect in a new column. For example, the computation of  $k = 5,000$  bootstrapping  
57  
58  
59  
60

1  
2  
3 subsamples entails the generation of  $k = 5,000$  products  $a \times b$  in a new column. Thereafter, the  
4  
5 standard deviation, which is equivalent to the standard error in bootstrapping ([Chernick, 2011](#)), can  
6  
7 be computed for the new column of the indirect effect  $a \times b$  to determine the standard error of its  
8  
9 distribution. [Hair et al. \(2016\)](#) explain this procedure in detail and provide an example that shows  
10  
11 how to conduct these computations. Using the standard error  $se$  of  $a \times b$  derived from the bootstrap  
12  
13 statistic, a pseudo  $t$ -test can be calculated to test whether the indirect effect  $a \times b$  is significantly  
14  
15 different from zero. Furthermore, based on the pseudo  $t$ -value, one can also calculate the  $p$  value.  
16  
17

18  
19  
20  
21  
22 [MacKinnon et al. \(2004\)](#) and [Wood \(2005\)](#) stated that more valid information about the  
23  
24 characteristics of the distribution of mediating effects is received by calculating a confidence  
25  
26 interval ( $ci$ ) for  $a \times b$  than with a pseudo  $t$ -value. For calculating a confidence interval ( $ci$ ), the  
27  
28 subsamples ( $k$ ) for  $a \times b$  from the bootstrapping procedure must be arranged from smallest to  
29  
30 largest ([Hayes, 2009](#)). A researcher has to select a specific alpha error; for example, for a  
31  
32 probability of error of 5%, a 95% confidence interval must be determined with a 2.5% probability  
33  
34 of error at each tail when conducting a two-sided test. The lower bound of  $a \times b$  is in the  
35  
36  $k \times (.5 - ci\% / 2)$ th ordinal position of the ordered list; for example, if one uses  $k = 5,000$   
37  
38 subsamples and a 95% confidence interval, the lower bound is the  $5,000 \times (.5 - 0.95 / 2) = 125$ th  
39  
40 ordinal position. Similarly, the  $(1 + k \times (.5 + ci\% / 2))$ th ordinal determines the upper bound of the  
41  
42 bootstrap confidence, which is the  $1 + 5,000 \times (.5 + 0.95 / 2) = 4,876$ th in the previous example.  
43  
44  
45  
46  
47 If  $zero$  is not included in the confidence interval, a researcher can assume that there is a significant  
48  
49 indirect effect  $a \times b$ .  
50  
51  
52  
53  
54

55  
56 Another problem often occurs when the mean of the bootstrapped distribution (i.e., sample mean  
57  
58 in most applications of the software tools (M)) for the indirect effect  $a_M \times b_M$  is not equal to the  
59  
60

1  
2  
3 estimated indirect effect (i.e., original sample in most of the software tools (O))  $a_O \times b_O$  ([Chernick, 2011](#)). As a result, researchers must correct for this bias in PLS, which can be accomplished by  
4  
5  
6 [2011](#)). As a result, researchers must correct for this bias in PLS, which can be accomplished by  
7  
8 calculating the difference between the estimated indirect effect  $a_O \times b_O$  from the path model and  
9  
10 the mean value of the indirect effect  $a_M \times b_M$  from the bootstrap sample. Consequently, the bias-  
11  
12 corrected  $ci\%$  confidence interval for an indirect effect  $a \times b$  can be defined as:

$$(2) \quad [(k \times (.5 - ci\%/2))th + (a_O \times b_O - a_M \times b_M); ((1 + k \times (.5 + ci\%/2))th + (a_O \times b_O - a_M \times b_M))].$$

13  
14  
15  
16  
17  
18  
19  
20  
21  
22  
23  
24  
25 [Hayes and Scharkow \(2013\)](#) show that the bias-corrected bootstrap confidence interval is the best  
26  
27 approach for detecting mediating effects when a mediating effect is present (i.e., Type-II error or  
28  
29 power). Conversely, the percentile bootstrap confidence interval that is not bias-corrected is a good  
30  
31 compromise if a researcher is also concerned about Type-I errors ([Hayes and Scharkow, 2013](#)).  
32  
33

34  
35  
36 Some researchers revert to Preacher and Hayes's ([2004](#)) macro and use the latent variable scores  
37  
38 from a PLS program to test indirect effects. This type of workaround is problematic in the context  
39  
40 of PLS. As mentioned above, PLS uses each bootstrap subsample to estimate the underlying PLS  
41  
42 path model. The bootstrap bases are the measurements of each construct: for a measurement with  
43  
44 five items, a separate bootstrap for each of these five items is performed. Using the latent variables  
45  
46 scores directly for the bootstrap procedure means fixing the bootstraps of the measurement model  
47  
48 and therefore not considering their variance. Hence, using Hayes's macro is less conservative.  
49  
50 Therefore, to also fully consider the variance in the measurement of a PLS path model estimation,  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60 researchers must directly rely on the bootstrapping results from the PLS software when testing  
61  
62 direct effects for significance ([Sosik et al., 2009](#), [Chin, 2010](#)).

### *Step 2: Determining the type of effect and/or of mediation*

Step 2 (Figure 2) involves defining the type of effect and/or mediation. A mediating effect always exists when the indirect effect  $a \times b$  in step 1 is significant. The current mediation literature discusses two different types of mediation, full and partial mediation. Partial mediation can be divided again into complementary and competitive partial mediation. We also discuss two effects that occur when the indirect effect is not significant, which means that only the direct effect is significant and no effect at all is significant. The latter cases do not represent a mediating effect in the narrow sense.

#### *a) Full Mediation*

A full mediation is indicated in the case where the direct effect  $c'$  is not significant whereas the indirect effect  $a \times b$  is significant, which means only the indirect effect via the mediator exists. In other words, full mediations means that the effect of the variable X to Y is completely transmitted with help of another variable M. It also means the condition Y completely absorbs the positive or negative effect of X. In this way, it can completely pass an effect or it can completely hinder the effect in terms of another effect. As an example, [Nitzl and Hirsch \(in press\)](#) show that in the trust relationship between a superior and a subordinate, the effect of the organization setting (X) to trust belief (Y) is fully mediated by the trustworthiness (M) of the subordinate. This finding shows that even in an organization setting (X) that may influence the trust relation between a superior and his/her subordinate in a positive way, the superior will not trust the subordinate when he/she is not trustworthy. Technically speaking, the variable X extracts his influence only under a certain condition of M on Y. However, in the case of small samples, a researcher is to exercise some caution when talking about full mediation. As [Rucker](#)

1  
2  
3 [et al. \(2011\)](#) showed, “the smaller the sample, the more likely mediation (when present) is to  
4 be labeled full as opposed to partial because  $c'$  is more easily rendered nonsignificant” (p. 364).  
5 Hence, it is advisable to ensure that the sample size is sufficiently large that the necessary power  
6 of 0.8 for an alpha level of 0.05 for detecting effects in a PLS path model is obtained ([Roldán](#)  
7 [and Sánchez-Franco, 2012](#), [Nitzl, in press](#)). For a simple mediation model such as that shown  
8 in Figure 1b, the necessary sample size is quite low, starting with 30 cases to detect strong  
9 effects, which is often the case in the context of experimental research (small sample per group  
10 and analyzing strong effects). Notwithstanding, a medium and small effect size would require  
11 a sample of 66 and 481 cases, respectively. In contrast, in many cases, it can be observed that  
12 some small direct effect  $c'$  remains even though the mediating effect is quite high in relation to  
13 the mediated direct effect. However, when this relation of the direct effect to the mediating  
14 effect becomes low but nevertheless stays significant, it can also be seen as full mediation. A  
15 researcher could indicate this with the help of the variance accountant for (VAF) value, which  
16 we will discuss in more detail below. Conversely, when the absolute value of the indirect path  
17  $a \times b$  is larger than the absolute value of the total effect  $a \times b + c'$ , there is a suppressor effect  
18 ([Cheung and Lau, 2008](#)); this situation could also be defined as full mediation ([Hair et al.,](#)  
19 [2016](#)).

#### 20 21 22 23 24 25 26 27 28 29 30 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 *b) Partial Mediation*

49 All other situations under the condition that both the direct effect  $c'$  and the indirect effect  $a \times b$   
50 are significant represent partial mediation. Two types of partial mediations can be distinguished:  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 i. *Complementary Partial Mediation*  
4

5 In a complementary partial mediation, the direct effect  $c'$  and indirect effect  $a \times b$  point in  
6 the same (positive or negative) direction ([Baron and Kenny, 1986](#)). It is an often observed  
7 result that  $a \times b$  and  $c'$  are significant and  $a \times b \times c'$  is positive, which indicates that a  
8 portion of the effect of X on Y is mediated through M, whereas X still explains a portion of  
9 Y that is independent of M. This complementary mediation hypothesis suggests that the  
10 intermediate variable explains, possibly confounds, or falsifies the relationships between the  
11 independent and dependent variables. Complementary partial mediation is often called a  
12 'positive confounding' or a 'consistent' model ([Zhao et al., 2010](#)). For example, [Nitzl and](#)  
13 [Hirsch \(in press\)](#) showed, in addition to the abovementioned full mediating effect, that 30%  
14 of the trust disposition (X) of a superior is mediated through the organizational (M) setting.  
15 Thus, the superior with a higher trust disposition (X) perceives the organizational context  
16 (M) to be more positive, which in turn positively influences whether a subordinate will be  
17 perceived as trustworthy (Y).  
18

30  
31  
32  
33  
34  
35  
36  
37  
38

39 ii. *Competitive Partial Mediation*  
40

41 In a competitive partial mediation, the direct effect  $c'$  and indirect effect  $a \times b$  point in a  
42 different direction. A negative  $a \times b \times c'$  value indicates the presence of competitive  
43 mediation in Step 2 (Figure 2). As mentioned above, this indicates that a portion of the effect  
44 of X on Y is mediated through M, whereas X still explains a portion of Y that is independent  
45 of M. In the past, researchers often focused only on complementary mediation ([Zhao et al.,](#)  
46 [2010](#)). In the competitive partial mediation hypothesis, it is assumed that the intermediate  
47 variable will reduce the magnitude of the relationship between the independent and  
48 dependent variables. However, it is possible that the intermediate variable could increase the  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 magnitude of the relationship between the independent and dependent variables. Competitive  
4  
5 partial mediation has often been called a ‘negative confounding’ or an ‘inconsistent’ model.  
6  
7 For example, [McFatter \(1979\)](#) suggested that intelligence (X) has a positive influence on  
8  
9 individual performance (Y); however, this effect could be suppressed by the task boredom  
10  
11 variable (M) because intelligence (X) leads to greater task boredom (M), and this variable  
12  
13 has a negative effect on individual performance (Y). In this vein, complementary and  
14  
15 competitive mediation are equally likely to occur, and each has the potential to deliver  
16  
17 theoretically interesting findings ([MacKinnon et al., 2007](#)). Thus, other types of mediation  
18  
19 beyond complementary mediation should be considered in a PLS path model.  
20  
21  
22  
23  
24  
25  
26

27 *c) Only Direct effect*

28  
29 If the indirect effect  $a \times b$  is not significant (i.e., the right path in the Figure 2 decision tree)  
30  
31 whereas the direct path  $c'$  is, the mediator variable has no impact; this indicates that a direct,  
32  
33 non-mediating effect is present. In this case, the study was perhaps searching for a wrong  
34  
35 mediation relationship. However, it is possible that an unrecognized mediation relationship still  
36  
37 exists and another mediation variable is present that mediates an effect between X and Y  
38  
39 ([Shrout and Bolger, 2002](#)). Thus, a researcher should rethink the model’s theoretical basis if  
40  
41 the expected mediation relationship cannot be found ([cf. Zhao et al., 2010](#)).  
42  
43  
44  
45  
46  
47  
48  
49

50 *d) No effect*

51  
52  
53 There is no effect if neither the indirect effect  $a \times b$  nor the direct effect  $c'$  is significant. The  
54  
55 total effect can still be significant. First of all, in this case, the researcher should determine  
56  
57 whether the sample size has enough power to show an effect when there is an effect ([Roldán](#)  
58  
59  
60

1  
2  
3 [and Sánchez-Franco, 2012, Nitzl, in press](#)). Putting the last two cases together – the indirect  
4 effect  $a \times b$  is not significant and the direct path  $c'$  is or is not – frequently indicates a  
5 problematic or flawed theoretical framework ([Zhao et al., 2010](#)). In this case, the researcher  
6 should thoroughly examine the hypothesized model. When, for example, the total effect  $c$  is  
7 significant, it can indicate that the mediation variable should be deleted because it brings no  
8 further degree of explanation. If the mediation variable  $M$  has no real effect, it only dilutes the  
9 effect of the direct variable  $X$  and should be deleted.

#### 24 **4. Additional Aspects for Assessing Mediation Models Fit and Strength in PLS**

25  
26 Before the background that mediation analysis mainly deals with explanation, a discussion of the  
27 use of goodness-of-fit indices is appropriate. The goodness of fit of a model is the ability of a PLS  
28 path model to reproduce the data. [Iacobucci et al. \(2007\)](#) emphasize that a good fit is required  
29 before interpreting mediation analysis in a structural model in the context of CB-SEM, which is in  
30 line with the general suggestion of [Henseler et al. \(2016\)](#) for PLS that it should also become  
31 customary for PLS to determine the model fit. According to [Wood et al. \(2008b\)](#), many authors  
32 inferred full mediation when a model excluding direct effect  $c'$  exhibited a better fit than a model  
33 including both direct  $c'$  and the indirect effects  $a \times b$ .  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46  
47

48 In the past, there were no valid criteria for evaluating the global fit of a PLS path model ([Henseler](#)  
49 [and Sarstedt, 2013](#)). Recently, to fill this gap, [Henseler et al. \(2014\)](#) introduced the fit index  
50 standardized root mean square residual (SRMR) for the context of PLS. A value below 0.08  
51 indicates that a PLS path model provides a sufficient fit of the empirical data ([cf. Hu and Bentler,](#)  
52 [1998](#)). [Williams and MacKinnon \(2008\)](#) argue that the CIs from resampling methods are a possible  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 solution to the distributional irregularities of the mediated effect. Therefore, it is good practice to  
4 report the upper quantile of the confidence interval of the bootstrap distribution of the SRMR,  
5 which [Henseler et al. \(2016\)](#) propose as an exact test of the model fit. Other indices that can be  
6 used for testing the exact fit are the geodesic discrepancy ( $d_G$ ) and the unweighted least squares  
7 discrepancy ( $d_{ULS}$ ) ([Dijkstra and Henseler, 2015](#)). Hence, the analysis of a mediation model in a  
8 PLS path model should start with the evaluation of the global fit to verify that all relevant effects  
9 are included in the structural model. Furthermore, in line with the abovementioned practice, a PLS  
10 researcher can use SRMR, for example, for inferring a full mediation when a model excluding  
11 direct effect  $c'$  exhibits a better fit than a model including both direct  $c'$  and indirect effects  $a \times b$ .  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21  
22  
23  
24  
25  
26

27 Beside the assessment of the model fit, PLS researchers might also be interested in evaluating the  
28 strength (portion) in case of a partial mediation. Mediation analysis regularly involves partial  
29 mediation, and therefore it can be helpful to have further information on the mediated portion. One  
30 approach for this is calculating the ratio of the indirect-to-total effect. This ratio is also known as  
31 the variance accounted for (VAF) value. VAF determine the extent to which the mediation process  
32 explains the dependent variable's variance. For a simple mediation, the proportion of mediation is  
33 defined (Figure 1) as:  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45

$$(3) \quad VAF = \frac{a \times b}{a \times b + c'}$$

46  
47  
48  
49  
50  
51  
52 Using VAF as classification for mediation portion is not uncritical. If the indirect effect is  
53 significant but does not mediate much of the total effect  $c$ , VAF would be low. As shown in Figure  
54 2, a significant indirect effect  $a \times b$  and insignificant direct effect  $c'$  would indicates a full  
55  
56  
57  
58  
59  
60

1  
2  
3 mediation. Such differences between significance testing and VAF interpretation especially occur  
4  
5 when samples sizes are small in terms of the power or a high multicollinearity between the  
6  
7 constructs exists ([Rucker et al., 2011](#)). A researcher should be aware that detecting an significant  
8  
9 indirect effect  $a \times b$  is always higher than detecting an direct effect  $c'$  ([Cohen, 1988](#)). The rule of  
10  
11 thumb is if the VAF is less than 20%, one should conclude that nearly zero mediation occurs; a  
12  
13 situation in which the VAF is larger than 20% and less than 80% could be characterized as a typical  
14  
15 partial mediation ([Hair et al., 2016](#)); and a VAF above 80% indicates a full mediation. However,  
16  
17 in this situation, the VAF may amount to, for example, only 60%, in which case researchers should  
18  
19 not assume full mediation.  
20  
21  
22  
23

24  
25  
26 Additionally, the interpretation of VAF is clear only for consistent or complementary mediating  
27  
28 effects (i.e.,  $c$  and  $a \times b$  having the same effects positive or negative). In one case, VAF can be  
29  
30 greater than one when the total effect  $c$  is smaller than the indirect effect  $a \times b$ ; this is the case for  
31  
32 a suppressor effect. In situations where the VAF is greater than one and the direct effect  $c'$  is not  
33  
34 significant; there is no strong indication that suppression is present. In this situation, [Shrout and](#)  
35  
36 [Bolger \(2002\)](#) suggest considering a VAF equal to 1 as representing a full mediation. In another  
37  
38 case, one could consider inconsistent mediation (i.e.,  $c$  and  $a \times b$  having different effects) as  
39  
40 yielding a negative VAF or a VAF tending to infinity as  $c$  approaches zero ([Hayes, 2009](#)).  
41  
42 Therefore, some researchers advise the calculation of VAF only when the absolute value of the  
43  
44 standardized total effect  $c = a \times b + c'$  is at least 0.2 ([Hair et al., 2016](#)). Thus, in general, VAF  
45  
46 may provide some deeper insights into mediation analysis but should be interpreted very cautiously  
47  
48 given the background of the above mentioned limitations.  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

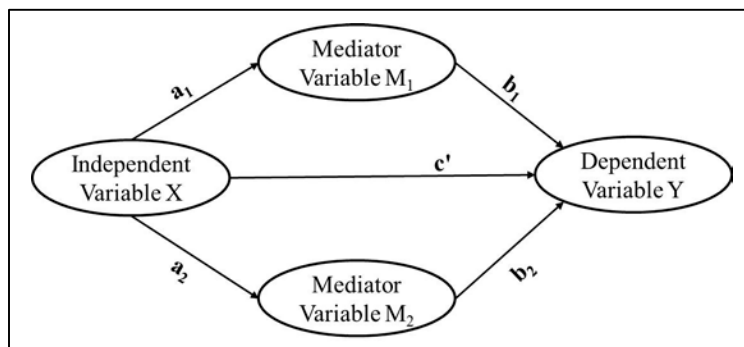

1  
2  
3 Some researchers measure the strength of mediation as its influence on the coefficient of  
4 determination  $R^2$  ([James and Brett, 1984](#)). However, a change in  $R^2$  says nothing about whether a  
5 mediator explains a portion of the relationship between an independent and a dependent variable  
6 ([Wood et al., 2008b](#)) because the amount of reduction in the effect of an independent variable due  
7 to a mediator variable is not equivalent to either the change in  $R^2$  or the change in the associated  
8 inferential statistics, such as the  $F$  value. The finding that  $R^2$  is significantly greater after including  
9 a mediator indicates only an additive effect. Therefore, the methods for measuring the mediation's  
10 strength should be based on the indirect effect.  
11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21  
22  
23

24 Furthermore, a researcher should not overlook important further aspects for the assessment of  
25 mediating effects in a PLS path model. An important precondition for analyzing mediating effects  
26 is that residuals (error terms) have to be uncorrelated; otherwise, they can heavily bias the results  
27 of the estimations ([McDonald, 1997](#)). In CB-SEM, the correlations between residuals can be  
28 followed by identification problems that have to be resolved using an unrealistic constraint of the  
29 error term with 0. In contrast, PLS as a soft modeling approach does not suffer from identification  
30 problems in the case of correlated residuals ([Falk and Miller, 1992](#)). PLS can suffer from a  
31 problematic bias in the estimation of the direct effect  $c'$ , which is similar to what [Henseler \(2012\)](#)  
32 shows for generalized structured component analysis (GSCA). The size of the bias depends on the  
33 reliability of the mediating construct. Hence, researchers should recognize the need for valid and  
34 reliable measurements when testing mediating effects in PLS.

## 5. Handling Multiple Mediations

PLS is regularly characterized by complex path models (Hair et al., 2012, Nitzl, in press). There may be multiple relationships between one or more independent variables, one or more mediator variables, or one or more dependent variables (for general SEM examples, see Wood et al., 2008a). For instance, a complementary mediation variable ( $M_1$ ) may mitigate the independent variable ( $X$ ) to a dependent variable ( $Y$ ), and at the same time, a competitive mediation variable ( $M_2$ ) may also exist. From a naïve perspective, someone can assume that the independent variable is not relevant because there is no relevant total effect  $c$ . However, when one of the mediator variables has a strong influence in a certain situation, the independent variable also wins in terms of relevance. Such areas can become very challenging, for example, when using a PLS path model to analyze which process improves or hinders the influence of the external pressure to work on performance. However, when more than one mediating effect is present, the abovementioned differentiation between direct and indirect effects for detecting mediation relationships remains applicable, and the above recommendations remain unchanged (Hayes, 2009).

Figure 3 presents an example of a PLS path model with two mediators.

**Figure 3:** Multiple Mediator Model

1  
2  
3 The total effect is equal to the direct effect of X on Y in addition to the sum of the indirect effect  
4 of M<sub>1</sub> and M<sub>2</sub>. A given mediator's indirect effect is referred to as a specific indirect effect (e.g.,  
5 through M<sub>1</sub>). The sum of the two specific indirect effects is the complete indirect effect. Thus, the  
6  
7  
8 total effect is the sum of the direct effect and the complete indirect effects (i.e., the sum of the  
9  
10  
11 specific indirect effects includes the relationship between M<sub>1</sub> and M<sub>2</sub>). For the example in Figure  
12  
13  
14  
15 3, the calculation of the total effect is:

16  
17  
18 (4) 
$$c = c' + a_1 \times b_1 + a_2 \times b_2.$$
  
19  
20

21 An interesting situation occurs (see our example above) when  $a_1 \times b_1$  and  $a_2 \times b_2$  in Equation 4  
22  
23 have an opposite sign; this indicates that one effect functions as a complementary effect, and the  
24  
25 other functions as a competitive mediator effect. Such a model is called an inconsistent mediation  
26  
27 model ([MacKinnon et al., 2007](#)). Consequently, even though significant specific indirect effects  
28  
29 exist, the complete indirect effect (e.g.,  $a_1 \times b_1 + a_2 \times b_2$ ) may not be significant.  
30  
31  
32  
33  
34

35 [Preacher and Hayes \(2008\)](#) argue that the incorporation of multiple mediators and the comparison  
36  
37 of their specific mediating effects is also useful for comparing different competing theories. Given  
38  
39 this background, researchers are interested in comparing the strengths of specific mediating effects  
40  
41 (e.g.,  $a_1 \times b_1$  and  $a_2 \times b_2$ ) in complex models ([Williams and MacKinnon, 2008](#)). For example, a  
42  
43 researcher could test for two complementary mediator variables if mediator (M<sub>1</sub>) has a stronger  
44  
45 mediator effect than mediator (M<sub>2</sub>). The previous explanation of how to compute bootstrap  
46  
47 confidence intervals in PLS can be extended to test the significance of the difference between two  
48  
49 specific mediating effects ([Lau and Cheung, 2012](#)). For that purpose, a researcher must calculate  
50  
51 the following equation:  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 (5) 
$$D_M = M_1 - M_2,$$
  
5  
6

7 where  $M_1$  and  $M_2$  are the specific indirect effects and  $D_M$  is the difference between these two  
8 specific indirect effects. In this way, we test whether two specific indirect effects are equal or if  
9 they amount to zero. In the case examined in this study, the equation for Figure 3 would be  
10  $D_M = a_1 \times b_1 - a_2 \times b_2$ . Again, researchers can calculate the equation using a spreadsheet  
11 application to build a confidence interval with the help of the bootstrapping results of PLS program.  
12  
13  
14  
15  
16  
17  
18  
19

20  
21 A frequently encountered case is one in which two mediators are connected to each other. This  
22 connection indicates an additional relationship between  $M_1$  and  $M_2$  in Figure 3. [Castro and Roldán](#)  
23 [\(2013\)](#) and [Klarner et al. \(2013\)](#) provide examples of how to test such multiple mediation  
24 relationships in a PLS path model. In such a case, the total effect  $c$  can be calculated as follows:  
25  $c = c' + a_1 \times b_1 + a_2 \times b_2 + a_1 \times a_3 \times b_2$ , where  $a_3$  stands for the relation between  $M_1$  and  $M_2$ .  
26  
27 An interesting case in this situation is when  $a_2$ ,  $b_2$ , and  $c'$  are not significantly different from zero,  
28 but the indirect effect  $a_1 \times a_3 \times b_2$  is (e.g., when  $M_1$  is the causal predecessor of  $M_2$ ); this would  
29 mean that  $M_1$  fully mediates the direct effect between  $X$  and  $M_2$  and that  $M_2$  fully mediates the  
30 direct effect between  $M_1$  and  $Y$ , thus establishing a direct causal chain  $X \rightarrow M_1 \rightarrow M_2 \rightarrow Y$  ([Mathieu](#)  
31 [et al., 2008](#)).

## 6. Conclusion

PLS applications must routinely account for mediating effects and apply state-of-the-art procedures. For this reason, we propose an alternative procedure for mediation analysis in PLS. Several articles using PLS applied at least some form of mediation. Although a few PLS studies already used a modern approach to test mediation, no study has yet presented a systematic overview and guideline of how to perform and classify a mediation analysis in a PLS path model context. PLS researchers are keenly interested in testing mediational hypotheses. However, they have used (if any) Baron and Kenny's (1986) approach, which is often criticized. Therefore, we have systematically transferred the recent findings from different research areas on mediation analysis to PLS. We summarize the findings more comprehensively and also evaluate their applicability for PLS, resulting in adjusted recommendations for mediation analysis in the context of PLS.

We illustrate that the characteristics of PLS require special consideration when analyzing mediating effects. PLS makes it necessary to test the relevant effects in one single model and not to follow a causal step approach for testing mediating effects, in which first a direct effect is tested and a mediator variable is included in the next step. Additionally, the bootstrap results for testing indirect effects have to be used directly from the PLS software because of fixed measurement problems when using only the values from the latent constructs that are included in another program. Moreover, caution is necessary when a mediation is indicated, however, in terms of additional assessments contradicting the classification guideline. The reasons for possible contradictions include small sample sizes or high multicollinearity.

With PLS, it is straightforward to estimate important extensions such as multiple mediators. With the help of the decomposition of total and indirect effects and testing these effects, a researcher can

1  
2  
3 gain deep insight into mediation processes of a PLS, which should become a standard approach for  
4  
5 PLS. For the sake of brevity, we do not include a concrete example where we show every aspect  
6  
7 that we discuss. Nevertheless, we regularly refer to concrete examples relevant to our research. In  
8  
9 general, good examples for mediation analysis can be found in [Chin \(2010\)](#) and [Streukens et al.](#)  
10  
11 [\(2010\)](#). In summary, this article provides researchers with a wide range of tools for performing  
12  
13 advanced mediation analysis in PLS that may improve theory development in different research  
14  
15 areas.
