Abstract

Flow Blurring® (FB) atomization is a highly efficient method to produce aerosols. It originates from an unexpected turbulent back flow motion in the interior of the atomizer. The onset for the appearance of such pattern is dictated by a geometrical parameter, φ, that is, the ratio of the distance between the tip of the liquid feeding tube and the discharge orifice (H), and the diameter of the discharge orifice (D). In this work, a FB atomizer with a nominal $\varphi = 1/6$ was used to produce water and ethanol droplets into pressurized environments (> 1 MPa). The droplet size distributions and mean droplet speeds were investigated using 1) direct visualization with an ultra-high speed video camera coupled with an automated droplet measurement (ADM) program and 2) using a light scattering instrument. Light scattering measurements, with water and ethanol, varying the driving pressure to produce the aerosol (ΔP), indicate a power dependence of ~2/5 of the dimensionless mean droplet diameter (D_{50}/D_o) on the dimensionless liquid flow rate (Q/Q_o). At higher liquid flow rate, the optical resolution of the droplets is improved compared to lower volumetric flow rates, thus facilitating analyses with the ADM program. The approach outlined herein provides a guideline for characterization and implementation of the FB technology in high-pressure applications.

KEYWORDS: Flow blurring, Liquid atomization, High pressure, Droplet size, Scaling parameter, High-speed video

Introduction

Liquid atomization requires conversion of a fraction of an energy input into surface energy. In pneumatic atomization, the interaction of gas and liquid flows is typically accompanied by turbulent motions that result in the generation of droplets of relatively small size. An efficient atomization is achieved by maximizing the surface area of the liquid flow and preventing droplet coalescence simultaneously minimizing the gas expense.

Gañán-Calvo (2005) proposed the so-called Flow Blurring® (FB) mechanism for efficient atomization of liquids. In FB, an unexpected back-flow pattern in the interior of the atomizer produces small scale perturbations, thus resulting in an efficient mixing between the gas and liquid phases (Gañán-Calvo, 2005) at the atomizer outlet. FB nozzle atomizers use a simple yet robust design in which the interaction of the liquid and gas flows is controlled by a geometrical parameter (φ), that is, the ratio H/D, where H is the gap between the tip of the liquid feeding tube (capillary) and the discharge orifice, and D is the diameter of the discharge orifice, as indicated in Figure 1a. The same geometrical configuration can lead to different modes of spraying only by varying φ. Relatively small values of φ lead to production of droplets with a wide range of sizes, in the FB mode. If; however, φ is increased above 0.6, the liquid flow forms a jet that, for a range of Weber numbers, is steady and breaks up periodically into monodisperse droplets, in what is known as flow focusing (FF) (Gañán-Calvo, 1998; 2005). The FB technique generates from five to fifty times more surface area than other methods, for a given energy input (Gañán-Calvo, 2005; Rosell-Llompart and Gañán-Calvo, 2008, Simmons and Agrawal, 2012). Such capabilities make FB nozzles suitable for many cutting-edge applications.

FB nozzles have been used in spectrometric techniques for generation of analyte droplets (Kovachev *et al.*, 2009; Aguirre *et al.*, 2010; Pereira *et al.*, 2014) and in atomization of biofuels (Simmons and Agrawal, 2012). Recently, we have proposed the direct atomization of water with FB nozzles into a combustion engine aiming at reduction of emissions (Modesto-López and Gañán-Calvo, 2017). The approaches to use water in combustion engines include either direct injection or

mixing with the fuel (Sahin *et al.*, 2014; Bedford *et al.*, 2000). In both cases, the size of the droplets is a key parameter influencing the droplets' evaporation timescale and their transport characteristics, and thus combustion efficiency as indicated by earlier studies (Hiroyasu and Kadota, 1976; Witting *et al.*, 1988). Most of the research on these topics has been performed at ambient or relatively low pressure conditions. However, FB in high-pressure environments, where many processes occur, remain largely unexplored. Thus, a detailed characterization of droplet size is of paramount importance to understand the spray dynamics.

Several tools for characterization of dense sprays are available, most of which are based on the interaction of the droplets with light. High-speed tomographic approaches are also employed for such systems where the dynamics of droplets or bubbles are demanding (Johansen, Hampel, and Hjertaker, 2009). Nevertheless, recently Tan, Gañán-Calvo and collaborators have developed a so-called automated droplet measurement (ADM) program for characterization of drops and bubbles in microfluidic systems (Chong *et al.*, 2016). Here, we also demonstrate that the same tool can provide, upon careful tuning of the program operation parameters, valuable information of high-throughput sprays, in which droplets are generally polydisperse and with varying velocities.

In this work, we study the characteristics of sprays in high-pressure environments produced by a FB nozzle. We coupled real-time visual methods with light scattering techniques to obtain the size distribution and the speed profile of the aerosol droplets in the vicinity of the FB nozzle. The key process parameters controlling FB atomization are the liquid flow rate, Q, the inlet gas pressure, P_o, the chamber pressure, P_i, and thus the pressure difference $\Delta P = P_o - P_i$. We also investigated a wide range of ΔP values for three different liquid flow rate to obtain a correlation in terms of dimensionless parameters.

Experimental Section

Materials

4

Deionized (DI) water (milliQ) and absolute ethanol (Sigma-Aldrich) were used as test fluids. The spraying nozzle consisted of a stainless steel (SS) body designed in-house, in which a commercial FB® nozzle tip (Ingeniatrics Tecnologías S. L., Sevilla, Spain) was assembled (Figure 1a). The tip, made of a corrosion resistant plastic (LCP), had a geometrical configuration as depicted in Figure 1a with the diameter of the discharge orifice, $D = 240$ µm; the distance from the exit of the liquid feeding capillary to the discharge orifice, $H = 40$ µm (nominal); and thus $\varphi = 1/6$. The internal and external diameters of the tip's liquid feeding capillary are $D_{ci,} = D$ and $D_{co} = 1$ mm, respectively. The angle of the discharge orifice, θ, is 120 °. Hereafter, the radial direction, r, is defined as the length from the centerline of the discharge orifice towards the exterior (see Figure 1a), and the axial direction, y, is the height from the discharge orifice downwards, in the direction of the spray. The AA' view of the FB tip is depicted in Figure S1 in the supporting information file.

Figure 1

Test Chamber

The in-house designed high-pressure chamber comprised three main components: 1) the FB nozzle (described above) and a corona to supply sheath gas, 2) a spray visualization section, and 3) a discharge converging flow region, as depicted in Figure 1b. The FB nozzle discharges into the visualization section, which consists of a cube with a cylindrical interior space. The cube had three circular perforations designed to house flat-surface, sapphire windows, thus allowing observation of the spray. The windows were purchased from IBSA LASER (Madrid, Spain) and were 5-mm thick with a diameter of 50 mm and were coated with an anti-reflective material on both planar surfaces. The sheath gas was introduced through a corona consisting of 40 cylindrical channels of 500 µm in diameter. The channels were distributed circularly around the FB nozzle and were fabricated in such a way to prevent direct interaction of the sheath gas with the spray. The gas flow rate was adjusted accordingly to achieve the desired chamber pressure. The discharge converging flow region, which

5

has a converging shape (see white lines in Figures 1a and 1b), had the function of accelerating the flow of the aerosol, thus preventing excessive droplets' accumulation in the visualization section. The pressure in the chamber was adjusted through head loss by gradually increasing the resistance of the exhaust tube. During all experiments, the pressure was measured at the gas inlet of the FB nozzle and in the chamber interior as depicted in Figures 1b and 1c. The measured pressures are gauge values, which were converted to absolute values for the calculations performed herein.

Ultra-high Speed Visualization Experiments

An ultra-high speed Shimadzu video camera (HPV-2), capable of recording up to 10^6 frames-per-second (fps), was focused through one of the sapphire windows, and illuminated with a high-intensity flash placed on the opposite side (Figure 1b). The flash was synchronized with the video camera through an external trigger. The camera began recording 1 ms after the trigger was manually switched on. DI water or ethanol was fed to the FB nozzle with a Shimadzu high-performance liquid chromatography (HPLC) pump (model LC-10AD). The gas inlet pressure (P_o) and chamber pressure (P_i) were monitored with digital, high-pressure WIKA manometers capable of measuring up to 10 MPa (model CPG1000). Additional gas was supplied through the 'corona' around the FB nozzle (see previous subsection), to increase the chamber pressure up to a desired value. The gas inlet pressure, P_o, was varied in the range 1.2 MPa to 5 MPa and, the chamber pressure, P_i, was maintained from 200 kPa to 3 MPa below P_o, as indicated in each set of measurements. Typical liquid flow rates, Q, used in this work were 0.3 mL/min and 0.5 mL/min (low range), 1 mL/min (medium range), and 5 mL/min (high range).

As-recorded ultra-high speed videos were processed with the widely known, freeware software ImageJ (Schneider *et al.*, 2012) to adjust their brightness/contrast and remove optical noise before being analyzed with the ADM program. Although, the processing step with ImageJ is generally unnecessary, in our case it is useful given the large number of droplets that simultaneously appear at any recording time. The frame of ultra-high speed videos had a field of view of 1.4 mm (width, x-

axis) x 1.2 mm (height, y-axis), which allows analyses in a region very close to the spray emission point. Besides its superior image processing capability, the ADM program has an inherent feature of background subtracting, thus removing optical artifacts which remain static through the sequence of frames, such as stains on the surfaces of lenses and windows. The ADM data reported herein are time-averaged values over the field of view. A brief description of the ADM program is included in the Supporting Information file. For detailed software setting parameters and operation conditions refer to Chong *et al.* (2016) and to the webpage link provided therein. The number-based droplet size distributions obtained with the ADM were converted to volume-based distributions to compare them with those from light scattering measurements.

Light Scattering Measurements (LSM)

Light scattering measurements (LSM) were performed with a Malvern Spraytec® instrument equipped with a 632.8-nm He-Ne laser of 15 mm in diameter and with a 300-nm range lens system capable of measuring particles with size in the range 0.1 µm to 900 µm. The detection system consists of 36 elements log-spaced silicon diode array. It has a maximum acquisition rate of 2.5 kHz (Rapid mode).

The high-pressure chamber was placed between the laser emitter and the detector lenses of the Spraytec, as shown in Figure 1c. Measurements were performed using Sprayect's internal trigger based on a transmission threshold, that is, the detectors started acquiring data once the light transmission level dropped to 70 % of the initial value. The data were recorded at a rate of 1 kHz and averaged over a period of, typically, 100 ms. The spray generation conditions were similar as those described in the previous section, that is, $\Delta P = 200$ kPa, 1 MPa, or 3 MPa; while Q was varied in the range $Q = 0.5 - 5$ mL/min. Note that measurements using a $Q = 0.3$ mL/min (similar to that in the high-speed visualization experiments) resulted in poor scattering signal, indicating that perhaps the liquid throughput was below the instrument's detection limit and thus $Q = 0.5$ mL/min was used instead. Nevertheless, an increment from 0.3 mL/min to 0.5 mL/min is expected to increase the mean

droplet diameter by less than 10 %, according to the FB model of Rosell-Llompart and Gañán-Calvo (2008).

Additionally, ancillary LS measurements, with DI water and ethanol, were carried out within a wide range of ΔP values (> 200 kPa, and P_o in the range 500 kPa - 6 MPa) to investigate the droplet size in high pressure environments as a function of process parameters.

Results and Discussion

Typical images of aerosols obtained with the ultra-high speed video camera are shown in Figure 2 for $\Delta P = 200$ kPa, $P_o = 4.2$ MPa, and $Q = 0.3$ mL/min (Figs. 2a and 2b), $Q = 1$ mL/min (Figs. 2c and 2d), and $Q = 5$ mL/min (Figs. 2d and 2f). The images correspond to a single frame out of hundred recorded. Figures 2b, 2d, and 2f are the magnified rectangles marked in Figures 2a, 2c, and 2e, respectively. As a guide, some of the droplets are circled with a dashed line. The presented images have been processed with the ImageJ software. Qualitatively, an increase in the droplet size is observed with rising of the liquid flow rate, as would be expected for mass and momentum conservation, which is particularly clear at the higher flow rate, $Q = 5$ mL/min (Figs. 2e and f). The size increase is also accompanied with an apparent broadening of the lower and upper size limits. The ADM program processes a sequence of 102 frames to track each droplet's position, average size, and speed in every frame while subtracting the static background. Note that the ADM was developed for microfluidics applications, where droplets' images are generally neatly defined. In dense sprays; however, there is a wide range of droplet sizes coming out simultaneously. For these cases, the accuracy of the ADM program depends on the quality of the recorded video. Thus, larger droplets with a sharp perimeter have higher probability of being detected by the software. Smaller droplets without a clear edge and poor contrast with their background go through, in some cases, undetected. Nevertheless, a careful manipulation of the ADM program's features still allows to obtain useful information from FB generated sprays, at least partially. Figure S2 shows a frame of a typical FB atomization extracted from a high-speed video and the observed motions are indicated by arrows. In

8

the image, the background, including optical artifacts and stains, has been removed with ImageJ, thus the black spots are individual droplets or groups of droplets. Although the image may appear blurry, it is the result of a processing with ImageJ to illustrate the overall fluid motions in the chamber. Along the centerline of the spray plume, at a radial distance of zero, there exists a high-speed zone which extends relatively far beyond the frame's vertical length (1.2 mm). At the periphery of the spray plume; however, a low speed zone (dashed ovals) is created, where relatively large droplets are observed. Furthermore, between the low and high speed zones there appears a motion from the periphery that accelerates droplets towards the inner part of the plume (curved, large arrows). In some videos, it is observed how droplets of relatively large size are pulled into the spray plume by this motion, from the exterior towards r = 0, and further accelerated downstream.

Figure 2

Droplet size distribution data from LSM and ADM analyses are discussed in this section. The number-based data collected with the ADM program were converted to a volume-based size distribution using a lognormal distribution function. Figure 3 shows volume-based droplet size distributions of aqueous aerosols generated with ΔP of 200 kPa (Figs. 3a-d), 1 MPa (Figure 3e), and 2 MPa (Figure 3f), with varying P_o, and low liquid flow rates, $Q = 0.3$ mL/min and $Q = 0.5$ mL/min for ADM and LSM, respectively. The red circles were obtained from analyses of high-speed videos with a frame width of 1.4 mm and height of 1.2 mm. Note that despite the difference in Q in these set of data, the variation in mean droplet diameter is expected to be less than 10 % based on the model developed by Rosell-Llompart and Gañán-Calvo (2008). In the four cases, with $\Delta P = 200$ kPa, the distributions obtained with ADM (red circles) match those from the curve of LS measurements (black line). With ADM, despite the relatively low liquid throughput (0.3 mL/min), a reasonably good size distribution is obtained. For the same Q, the aerosol concentration laid below the detection limit of the LS instrument, as confirmed through many measurements where no reliable signal was obtained. The

9

accuracy of the ADM program may be improved by using higher magnification lenses during recording, at the expense of reducing the field of view. The mean droplet diameter and geometric standard deviation recorded through LSM are summarized in Table 1. For constant ΔP (200 kPa) and Q (0.5 mL/min), there seems to be an apparent increase in mean droplet diameter from 8 μm at P_o = 1.2 MPa to 10 μm at P_o = 4.2 MPa, although such variation may be within the experimental error. Additionally, the standard deviation appears as though it varies slightly from 0.7 down to 0.6 for the same pressure range, thus indicating narrowing of the distribution. That is, for a constant ΔP (and also Q) the mean diameter is not expected to vary significantly. Conversely, as ΔP is increased up to 1 and 2 MPa the mean droplet diameter shifts towards smaller sizes. Such downsize is accompanied by a slight broadening of the distribution, as evidenced by a rise of the standard deviation from ~ 0.55 to ~ 0.70: a bigger ΔP obviously implies not only a larger amount of turbulent energy invested in surface generation per unit liquid volume, but also a wider range of length scales of the turbulent energy cascade.

Table 1

Figure 3

In the case of Q = 1 mL/min for ΔP = 200 kPa and varying P_o, the size distributions obtained with ADM fall again under the curve of the LSM, indicating a relatively good correlation (Figure 4). For these set of data, too, increasing P_o from 1.2 MPa to 4.2 MPa apparently raised the mean droplet diameter by nearly 3 μm and the distributions also undergo a slight narrowing, as indicated by a decreasing of the standard deviation (Table 1). Again, as in the previous case, the increase may be within experimental error. For ΔP of 1 MPa and 2 MPa, the mean droplet diameter is smaller than that of ΔP = 200 kPa and the diameter reduction is also accompanied by a broadening of the distribution; as mentioned above, bigger ΔP means larger turbulent energy input, thus resulting in larger liquid

10

surfaces (i.e., smaller droplets) with wider range of scales. Furthermore, the mean diameters are larger than those obtained with $Q = 0.5$ mL/min, for the same ΔP, consistently with the expected decrease of surface generated per unit volume (i.e. the inverse of the Sauter Mean Diameter) under the same energy input.

Figure 4

As Q is further increased up to 5 mL/min, for a ΔP of 200 kPa, LSM and ADM analyses match closely (Figure 5). Such results may arise, partially, due to an increase in the size of the droplets, thus improving the resolution of the analyses with ADM. Note also that while LSM produces a relatively smooth curve, ADM analyses generate discrete sizes and are dependent on the counts of droplets in each frame. However, in the distributions presented herein, the data have been converted to a lognormal distribution. The mean droplet diameter shows an irregular trend for the range of P_o explored in the current work. Compared to the smaller Q cases, the larger mean sizes obtained in this data set is justified by an increase in the mass of liquid supplied to the system.

Figure 5

Furthermore, the droplets' speed was investigated with ADM. The average droplet speed distributions of the cases discussed above are shown in Figures 6, 7, and 8 for $Q = 0.3$ mL/min, $Q = 1$ mL/min, and $Q = 5$ mL/min, respectively. The speed has been made non-dimensional by the theoretical speed, V_{th}, of the gas exiting through the geometrical gap with dimension H, the so-called lateral cylindrical passageway (LCP) (Gañán-Calvo, 2005), as depicted in Figure 1a. V_{th} was calculated using Equation (1) below and assuming adiabatic expansion of the gas as it exits to the pressurized environment, and the values are listed in Table 1:

$$V_{th} = M \left(\gamma \frac{R}{m} T \right)^{1/2} \qquad (1),$$

11

where M is the Mach number, γ is the adiabatic expansion coefficient, R is the ideal gas constant, m is the molecular weight of the gas, and T is the absolute temperature of the gas at the exit. Since $M = 1$ for a convergent discharge geometry like the one considered here, then $V_{th} = \left(\frac{2\gamma}{\gamma+1}\frac{R}{m}T_o\right)^{1/2}$, where T_o is the ambient temperature. For the cases with low P_o and low/medium Q values (Figs 6a-b and 7a-b), the distribution depicts a nearly flat profile along the centerline of the spray, that is, at a radial distance of zero, and the speeds in that region are much smaller than V_{th}.

Figure 6

As P_o is increased, still for low/medium Q values (Figs. 6c and 7c), the flat front disappears and instead the distributions become sharper, with the maximum speed being achieved at a radial distance of r = 0. In those cases, the maximum measured mean speed reaches nearly the 20 % of V_{th}. Further increase of P_o up to 4.2 MPa, for the same flow rates (Figs. 6d and 7d), results in speed distributions with a marked sharp profile, where the maximum speed was attained at a radial distance of zero, that is along the centerline of the spray plume, and with values of the order of 30 % of the theoretical speed. For the cases with $\Delta P \geq 1$ MPa and low/medium values of Q (Figs. 6e-f and 7e-f), the distributions are significantly different to the previous cases. It appears as if the droplets, particularly, in the central region (r =0) of the plume, move faster than the recording threshold speed of the video camera. Indeed, the maximum speed values detected with the ADM program do not reach the 10 % of the theoretical speed. In the case of the highest Q (5 mL/min), the speed distributions clearly show a sharp profile (Figures 8a-d), even for the lowest P_o case, which at lower flow rates showed a flat profile.

Figure 7

12

However, the maximum measured speeds still do not reach their theoretical values. Even when P_o is increased > 3.2 MPa, droplets in the plume at a radial distance of zero reach approximately 25 % of V_{th}. The speed distributions (for $\Delta P = 200$ kPa) have been fitted with Gaussian profiles (blue line) and it appears they correlate well, except for the data set where the speed profile is nearly flat (Figure 6a). The speed data obtained with ADM agrees qualitatively with FB results reported by other authors (Jiang and Agrawal, 2015; Fisher *et al.*, 2017; and Niguse and Agrawal, 2017). They as well observe a maximum at the radial distance of zero. Fisher *et al* (2017) also report a sharp speed profile in the region near the spray emission point and it transitions to a flat profile at an axial position further away from the emission point (100 mm).

Figure 8

Gañán-Calvo (2005) derived a scaling law for FB at ambient pressure (P_i) in terms of Weber (We) and Ohnesorge (Oh) numbers, and the gas-to-liquid mass ratio (GLR) in the atomizer. The We have been calculated with $\rho_g U_g^2 D(2\sigma)^{-1}$ and using the gas density (ρ_g) and velocity ($U_g = V_{th}$) at the exit of the LCP assuming adiabatic expansion of the gas. Surface tension values, σ, of water and ethanol were calculated as a function of the temperature at the exit of the LCP. The Ohnesorge number, Oh, is given by $\mu(\rho_l \sigma D)^{-1/2}$, where μ and ρ_l are the liquid viscosity and density, respectively. The expression of Gañán-Calvo (2005), Equation (2), relates a measured mass median diameter (MMD), through a dimensionless parameter δ (= MMD/D), with the dimensionless quantities: We, Oh, and GLR.

$$\delta = 0.42We^{-0.6}(1 + 18Oh)(1 + GLR^{-1})^{1.2} \qquad (2)$$

In Figure 9a, we have plotted a similar relationship using a dimensionless parameter, δ^*. That is, the blue circle data points were obtained with $\delta_1^* = \text{MMD}_{exp}/D$, where the MMD_{exp} was calculated from our experimental D_{50} data with $MMD_{exp} = D_{50}e^{-0.5(ln\sigma_g)^2}$ and using the geometric standard deviation of the distribution, σ_g. In the case of the green squares, δ_2^* was calculated by introducing a $(D_{50}/D)^{1/3}$ factor to the expression of Gañán-Calvo (2005), that is, $\delta_2^* = 0.42(D_{50}/D)^{1/3}We^{-0.6}(1 +$

$18Oh)(1 + GLR^{-1})^{1.2}$. The closed symbols in the plot correspond to data at $M \geq 1$. In Figure 9a, the black, solid line shows the model of Gañán-Calvo (2005) for FB at relatively low pressure conditions. The data points calculated using δ_1^* (MMD$_{exp}$) spread above the FB model and they appear to be independent of the Mach number. Although, the data follow the general trend of the FB model, there is a relatively large dispersion around a power fit (black, dashed line), which results in $\delta_1^* We^{0.6}/(1 + 18Oh) = 0.95 + 1.3GLR^{-1.15}$. Conversely, data points calculated with δ_2^* are aligned below the FB model and the data collapse is improved, compared to the δ_1^* case, resulting in a power fit (black, dotted line) of $\delta_2^* We^{0.6}/(1 + 18Oh) = 0.10 + 2.8GLR^{-1.15}$. In this data set, too, the trend appears to be independent of the Mach number.

Figure 9

Another scaling relationship is established by the dimensionless mean droplet diameter D_{50}/D_o as function of the dimensionless liquid flow rate Q/Q_o, which is plotted in Figure 9b, where $D_o = \sigma/\Delta P$ and $Q_o = (\sigma^4/\rho_l \Delta P^3)^{1/2}$ are of the order of the minimum attainable diameter and flow rate, respectively (Rosell-Llompart and Gañán-Calvo, 2008). The blue, closed circles correspond to data of ethanol. In the same graph, the lowest limit of a FB model, at relatively low pressure, by Rosell-Llompart and Gañán-Calvo (2008) is also plotted (black solid line) along with an upper boundary set by the so-called Rayleigh + Flow Focusing regime (green, dotted line), in which a liquid micro jet breaks up by growth of axisymmetric waves at a critical hydrodynamic We. Our data lays out between both limits, similarly as reported by Rosell-Llompart and Gañán-Calvo (2008), thus indicating the occurrence of the flow blurring phenomenon. A fitting of the data gives $(D_{50}/D_o) = 0.47(Q/Q_o)^{0.45}$. Note the exponent of approximately 2/5, for the pressure range measured in this work, which is 1/5 for the lower limit as established by the FB model (Rosell-Llompart and Gañán-Calvo, 2008). In Figure 9c we have plotted a dimensionless droplet diameter (D_{50}/D) as a function of We, Oh, the GLR, and the Mach number, which are parameters strongly affecting the described FB process. The blue circles

indicate data points recorded at M $\geq$ 1. A relatively good collapse of the data is observed independently of the liquids' properties and the pressure conditions (subsonic or supersonic). The data are fitted by the expression $(D_{50}/D) = 0.005 + 0.023(We^{0.5}Oh\ GLR\ M)^{-0.46}$. In Figure 9d, D_{50}/D_o is depicted as function of Q/Q_o, GLR, and M. In this case, a slightly improved data collapse is observed with respect to Figure 9b, in which D_{50}/D_o is a sole function Q/Q_o. A power fit results in an exponent of approximately ~1/2 for our experimental data. The proposed scaling expressions relate D_{50} and MMD to the main parameters of FB atomization in high pressure environments. They provide a guideline for the analyses of droplet sizes in such conditions.

Conclusions

Aqueous and ethanol aerosols produced by a FB® nebulizer under high pressure conditions have been investigated both with direct visualization, using an ultra-high speed video camera coupled with an in-house developed program, and with light scattering measurements. The ADM program, typically used for analyses of micro-fluidic systems, was successfully applied to aerosols with relatively high throughput and turbulent motions. Droplet size distributions obtained with the ADM program are comparable to those obtained with LSM. Particularly, a good fit is found at the highest liquid flow rate, where the droplets are larger and can be readily detected during image processing. With LS instrument, mean droplet diameters in the range 8 μm - 26 μm were obtained with a ΔP = 200 kPa and liquid flow rates in the range 0.3 - 5 mL/min. Increasing ΔP up to 1 MPa and 2 MPa caused a significant reduction of the mean droplet diameter. As P_o is increased (constant ΔP = 200 kPa) the mean droplet speed shifts from a relatively flat profile at low Q to a sharp distribution at medium Q. At high liquid flow rate; however, the mean droplet speed approaches a Gaussian distribution, even for low P_o values. Fitting of a number of FB experiments (φ = 1/6) for ΔP in the range 200 kPa - 3 MPa, and P_o as low as 500 kPa, result in $(D_{50}/D_o) = 0.47\ (Q/Q_o)^{0.45}$. The experimental mass median diameter obtained at high pressure conditions appears to have a similar trend as the FB scaling law of Gañán-Calvo (2005) for atmospheric discharge pressure (P_i). Based on

the same scaling law, a modified parameter in terms of $(D_{50}/D)^{1/3}$ was proposed to fit the data as a function of the gas-to-liquid mass ratio. In addition, other scaling relationships for the mean droplet diameter of sprays produced by FB at relatively high pressure conditions were established, which incorporate the effect of the external pressure through the Mach number. The approach presented in this study may be a guideline for implementation of FB in high-pressure applications, for instance, in combustion technology.

FIGURE CAPTIONS

Figure 1. a) Diagram of a cross-sectional view of the FB tip. Schematics of the experimental setup used for b) high-speed visualization experiments and c) light-scattering measurements.

Figure 2. Photographs of water aerosols recorded with the ultra-high speed camera for $\Delta P = 200$ kPa, $P_o = 4.2$ MPa, and $Q = 0.3$ mL/min (a and b), $Q = 1$ mL/min (c and d), and $Q = 5$ mL/min (e and f). The white line at the top indicates the nebulizer's tip. Images b, d, and f are magnified views of the rectangles in images a, b, and c, respectively.

Figure 3. Particle size distributions of water droplets obtained with the ADM program (red circles, $Q = 0.3$ mL/min) and with light scattering (black line, $Q = 0.5$ mL/min) at $\Delta P = 200$ kPa, and P_o of a) 1.2 MPa, b) 2.2 MPa, c) 3.2 MPa, and d) 4.2 MPa; e) $\Delta P = 1$ MPa ($P_o = 4$ MPa); f) $\Delta P = 2$ MPa ($P_o = 5$ MPa).

Figure 4. Particle size distributions of water droplets obtained with the ADM program (red circles) and with light scattering (black line) at $Q = 1$ mL/min, $\Delta P = 200$ kPa, and P_o of a) 1.2 MPa, b) 2.2 MPa, c) 3.2 MPa, and d) 4.2 MPa; e) $\Delta P = 1$ MPa ($P_o = 4$ MPa); f) $\Delta P = 2$ MPa ($P_o = 5$ MPa).

Figure 5. Particle size distributions of water droplets obtained with the ADM program (red circles) and with light scattering (black line) at $Q = 5$ mL/min, $\Delta P = 200$ kPa, and P_o of a) 1.2 MPa, b) 2.2 MPa, c) 3.2 MPa, and d) 4.2 MPa.

Figure 6. Average speed profile of water droplets obtained with the ADM at Q = 0.3 mL/min and ΔP = 200 kPa, and P_o of a) 1.2 MPa, b) 2.2 MPa, c) 3.2 MPa, and d) 4.2 MPa; e) ΔP = 1 MPa (P_o = 4 MPa); f) ΔP = 2 MPa (P_o = 5 MPa).

Figure 7. Average speed profile of water droplets obtained with the ADM at Q = 1 mL/min and ΔP = 200 kPa, and P_o of a) 1.2 MPa, b) 2.2 MPa, c) 3.2 MPa, and d) 4.2 MPa; e) ΔP = 1 MPa (P_o = 4 MPa); f) ΔP = 2 MPa (P_o = 5 MPa).

Figure 8. Average speed profile of water droplets obtained with the ADM at Q = 5 mL/min and ΔP = 200 kPa, and P_o of a) 1.2 MPa, b) 2.2 MPa, c) 3.2 MPa, and d) 4.2 MPa.

Figure 9. a) $\delta^* We^{0.6}(1 + 18Oh)^{-1}$ as function of GLR, where δ^* is given by MMD/D (blue circles) and $0.42(D_{50}/D)^{1/3}We^{-0.6}(1 + 18Oh)(1 + GLR^{-1})^{1.2}$ (green squares). The black solid line depicts the model of Gañán-Calvo (2005). The closed symbols correspond to data at M ≥ 1. Red symbols are data of ethanol. b) Dimensionless average mean diameter, (D_{50}/D_o), as a function of the dimensionless liquid flow rate, (Q/Q_o). The blue, closed circles indicate data of ethanol. The dashed, blue line shows a power fitting $(D_{50}/D_o) = 0.47(Q/Q_o)^{0.45}$. The black line depicts the lowest limit of the FB model and the green, dotted line shows the upper boundary delimited by the Rayleigh + Flow Focusing regime. c) (D_{50}/D) as a function of $We^{0.5}Oh\ GLR\ M$. The blue circles are data points at M ≥ 1 and the green circles are data of ethanol. d) (D_{50}/D_o) plotted as a function of $(Q/Q_o)(1 + GLR^{-1})^{0.3}M^{-0.6}$. The closed, blue circles correspond to data of ethanol.

Visualization and Size-Measurement of Droplets Generated by Flow Blurring® in a High-Pressure Environment

Luis B. Modesto-López* and Alfonso M. Gañán-Calvo

*Contact: lmodesto@us.es
1. Schematics of Flow Blurring tip

Figure S1. AA' view of FB tip (see Figure 1a in main text)

1. **Automated Droplet Measurement (ADM) program**

A brief description of the ADM program is provided here. For further details on the functioning of the program, readers are encouraged to refer to 'Chong Z. Z., Tor S. B., Gañán-Calvo A. M., Chong Z. J., Loh N. H., and Nguyen N. T. (2016). Automated droplet measurement (ADM): an enhanced video processing software for rapid droplet measurements. Microfluid. Nanofluid., 20:66' and to the website http://a-d-m.weebly.com/ from where ADM can be freely obtained.

The ADM software addresses bottlenecks that hinder the currently available software to perform rapid droplet measurements, such as processing speed. The program incorporates background as well as threshold finding algorithms, thus eliminating the need to perform those processes manually.

General ADM program operation steps:

1.1 First, the user must select a number of operation parameters, being the following crucial for our purposes: droplet circularity (where the value of 1 represents a perfect circle), video recording speed, size range (in pixels) of droplets to be analyzed, and the scale of the video (i.e., the length in μm per pixel). The procedure to find the operation parameters that best suit the video recording conditions is based on trial and error. In addition, the user may select the parameters that would like to analyze, such as droplet equivalent diameter and droplet speed. They may be reported as timely-averaged over the entire video duration.

1.2 Then, the program performs the background extraction operation (BEO) automatically, using the as-recorded video, thus taking into account the experimental conditions under which the video was taken and eliminating the need to acquire a background for every experimental condition. Here, background refers to chamber walls, stains, and optical artifacts, that is, still or non-moving objects.

1.3 The ADM software then performs the analyses. It identifies the droplets (i.e., their contour) based on the operation parameters introduced in 1.1 and assigns them an 'object number'. The software then tracks the position of each droplet on each video frame to obtain their trajectory. The droplet equivalent diameter is calculated with:

$$\sqrt{\frac{4 \times (number\ of\ pixels)^2 \times (\mu m/pixel)^2}{\pi}}$$

The droplet speed (that is the speed of the centroid of the droplet) is calculated with:

$$\sqrt{(velocity\ in\ X)^2 + (velocity\ in\ Y)^2}$$

and updated every video frame. Here X and Y refer to the horizontal (width of the video frame) and vertical (height of the video frame) directions, respectively.

2. **FB spray motion in high pressure chamber**

2

Figure S2. Images from ultra-high speed videos to illustrate overall spray motions in the high-pressure chamber, recorded at different magnifications. The liquid is deionized water. a) lens zoom = 5.0x, and Po = 5 MPa, Pi = 3 MPa, Q = 5 mL/min; and b) lens zoom = 1.25x, and Po = 4.5MPa, Pi = 0.5 MPa, Q = 3 mL/min.
