Abstract

Organic-inorganic hybrid materials were synthesized by controlled hydrolysis of tetraethoxysilane (TEOS), methyltrimethoxysilane (MTES), synthetic wollastonite powders and polydimethylsiloxane (PDMS) in an ethanol solution. Aerogels were prepared from acid hydrolysis of TEOS and MTES with different volume ratio in ethanol, followed by addition of wollastonite powder and PDMS in order to obtain aerogels with 20 wt % of PDMS and 5 wt % of CaO of the total silica. Finally, when the wet gels were obtained, they were supercritically dried at 260 °C and 90 bar, in ethanol. In order to obtain its bioactivity, one method for surface activation is based on a wet chemical alkaline treatment. The particular interest of this study is that we introduce hybrid aerogels, in a 1 M solution of NaOH, for 30 s at room temperature. We evaluate the bioactivity of TEOS-MTES aerogel when immersed in a static volume of simulated body fluid (SBF). An apatite layer of spherical-shaped particles of uniform size smaller than 5 microns is observed to form on the surface of the aerogels after 25 days soaking in SBF.

Keywords: organic-inorganic hybrid, aerogel, wollastonite, composite, bioactive materials, mechanical properties.

Introduction

Organic-inorganic hybrid materials (OIHM) obtained from tetraethoxysilane and methyltriethoxysilane (TEOS-MTES systems) have been extensively studied as matrices for different functional molecules. They offer many potential applications as porous films with low dielectric constant, hydrophobic membranes with very high gas permeability for CO₂, and coatings with interesting mechanical properties [1,2,3,4,5]. OIHM obtained from TEOS, MTES and poly-dimethyl-siloxane (PDMS) present a lower porosity and higher rupture strength than TEOS-MTES gels, and can be used for their optical, electrical and catalytic properties [6].

Porous bioactive glasses are potentially useful materials for orthopaedic applications. Their porosity is an important characteristic since it allows vascular penetration and subsequent neo-bone growth. A high surface-to-volume ratio helps to make these materials biodegradable and bioactive, permitting an apatite-like layer to grow when in contact with body fluid [7].

Silica gels derived from the sol-gel process have a high surface area and porosity and have been shown to be far more effective in inducing hydroxyapatite formation than either silica glass or quartz [8]. The

1 textural properties play a crucial role in governing the bioactivity of these materials. Silica aerogels are
2
3 nanostructured, transparent, chemically inert and highly porous materials. The density of these aerogels
4
5 may vary from $0.0019 \text{ g}\cdot\text{cm}^{-3}$ to $0.9 \text{ g}\cdot\text{cm}^{-3}$ [9], with a high porosity, close to 90 %, with pores of
6
7 nanometric size that give rise to specific surfaces of between 600 and $1000 \text{ m}^2\cdot\text{g}^{-1}$, and their composition
8
9 stays identical to that of vitreous silica [10,11]. Their main limitations are fragility and high
10
11 hygroscopicity.
12
13

14
15 In recent years, organically-modified ceramics from gels have been attracting much attention as a new
16
17 family of hybrid materials. In these materials, organic polymers are chemically incorporated into the
18
19 inorganic network at the molecular level. As a result, unique mechanical properties can be derived,
20
21 particularly a low elastic modulus and high ductility combined with high mechanical strength. It is
22
23 widely believed that such hybrid materials present unique applications as a new kind of bioactive
24
25 material [12].
26
27

28
29 Wollastonite is a natural calcium silicate, which has been used extensively as filler in polymers and
30
31 cements, to fabricate composites with improved mechanical properties. Recent studies have shown that
32
33 wollastonite is bioactive and degradable; consequently it has potential use as a bioactive material in
34
35 tissue repair or tissue engineering research [13].
36
37

38
39 Different metal pre-treatment and coating methods, such as alkaline or acid treatment, or using H_2O_2 ,
40
41 and sol-gel coating of TiO_2 , have been used by various research groups in an attempt to form such a
42
43 bioactive surface on Ti plates. Kim *et al.* [14] reported that amorphous sodium titanate hydrogel,
44
45 obtained by exposing pure Ti to an alkaline solution and subsequently to heat treatment, would induce
46
47 apatite formation when soaked for a period of time in SBF. They showed that pure Ti metal formed a
48
49 bonelike apatite layer on its surface in SBF within 3 days after being prepared, by soaking in a 5 M
50
51 solution of NaOH at $60 \text{ }^\circ\text{C}$ for 24 h with subsequent heat treatment at $600 \text{ }^\circ\text{C}$ for 1 h [15]. Other authors
52
53 have reported that, in order to induce nucleation of the Ti with 1 - 20 M solutions of NaOH, it was
54
55 exposed to temperatures of 60 - $95 \text{ }^\circ\text{C}$ for 24 h. In some cases it has been concluded that the immersion
56
57 in a 5 M solution of NaOH at $80 \text{ }^\circ\text{C}$ for 24 h is the optimum treatment [16,17].
58
59
60
61
62
63
64
65

1 The objective of the present study is to synthesize hybrid bioactive aerogels, whose inorganic phase is
2
3 SiO₂ and the organic phase is PDMS and the methyl groups that remain bound to silicon after the MTES
4
5 hydrolysis. Synthetic wollastonite powders are used as the bioactive phase. They received a surface
6
7 treatment that induces the formation of the hydroxyapatite nucleus. This treatment consisted of
8
9 maintaining the aerogels in an alkaline solution (NaOH, 1M) at room temperature for 30 s. Studies of the
10
11 resulting bioactivity and mechanical properties were also carried out, and the results were compared
12
13 with those for human cancellous bone to evaluate its potential application for bone substitution or
14
15 regeneration.
16
17
18

20 **2. Materials and methods**

22 **2.1. Sample preparation**

24 Silica-based organic-inorganic hybrid gels were synthesized by the classic sol-gel method using a two-
25
26 step procedure. First, TEOS and MTES (both reagents from Merck, Germany; purity $\geq 99\%$), were used
27
28 as inorganic and organic phase precursors, respectively. We have combined different amounts of TEOS
29
30 and MTES, with the following TEOS:MTES volume ratios: 9:1, 5:5 and 1:9. They were hydrolysed
31
32 under-stoichiometrically with acidic water (pH ~ 1) in a molar ratio $[\text{TEOS}+\text{MTES}]:[\text{H}_2\text{O}] = 1:0.84$. At
33
34 this stage, $320 \text{ J}\cdot\text{cm}^{-3}$ of ultrasound was applied to the mix from a device delivering $0.6 \text{ W}\cdot\text{cm}^{-3}$ of
35
36 ultrasound power energy to the system, giving a transparent and homogeneous solution.
37
38
39

41 In the second step, silanol-terminated poly-dimethyl-siloxane (PDMS) with quoted average molecular
42
43 weight of $400 - 700 \text{ g}\cdot\text{mol}^{-1}$ (ABCR, USA; 99.5 %) was used as the polymer component. This organic
44
45 polymer was added (drop by drop, under the action of $320 \text{ J}\cdot\text{cm}^{-3}$ of ultrasound) in a molar ratio
46
47 $[\text{TEOS}]:[\text{DMS}] = 1:0.027$ (representing $\sim 20\%$ by weight of PDMS with respect to the final amount of
48
49 silica), where the organic fraction has been expressed as a function of the dimethyl-siloxane monomer,
50
51 DMS. Then the sol was left in an oven for 24 h at 50°C . The mix was hydrolysed (pH ~ 1) with HNO₃
52
53 catalyst (Panreac, Spain; purity 60 % by vol.) in a molar ratio $[\text{TEOS}]:[\text{H}_2\text{O}] = 1:3.16$, again applying
54
55 $320 \text{ J}\cdot\text{cm}^{-3}$ of ultrasound energy. Synthetic wollastonite powders (CaSiO₃) [9] were used as a bioactive
56
57 phase. The appropriate amount of wollastonite (to give a Ca content of 5 % by weight with respect to
58
59
60
61
62
63
64
65

1 the total amount of silica) was dispersed in 75 ml of EtOH per gram of wollastonite and then added to
2
3 the precursor sol under sonication ($320 \text{ J}\cdot\text{cm}^{-3}$). The mixture was poured into a polyethylene container
4
5 before gelation, which occurs in approximately one minute, thus preventing the powder from settling.
6
7 Then the container was left in an oven at $50 \text{ }^\circ\text{C}$ for 24 h. Next, the alkogels were soaked in ethanol at
8
9 room temperature for 7 days for aging and removing the residual water from the pores.
10

11
12 At this point the gel is placed in an autoclave and the pore liquor is vented-off above the supercritical
13
14 conditions of ethanol ($240 \text{ }^\circ\text{C}$, 63 bar). The supercritical state is attained by slow heating ($1 \text{ }^\circ\text{C}/\text{min}$) in
15
16 order to minimize the ethanol thermal expansion coefficient, which is much greater than that of the wet
17
18 silica gel network. Then the heating produces the evaporation of the additional volume of ethanol that
19
20 allows the supercritical pressure and temperature ($255 \text{ }^\circ\text{C}$, 85 bar) to be reached, in such a way that the
21
22 vapour-liquid equilibrium curve is never crossed, to avoid capillary pressures on the adjacent pore. Thus
23
24 the structure does not collapse and the aerogel retains its original shape. As a provision for the
25
26 mechanical test, samples were made as cylinders of approximately 18 mm length and 8 mm diameter.
27
28 Density was calculated by weighing the sample with a well-defined geometry.
29
30
31
32

33
34 In order to facilitate the bioactivity of aerogels, we applied an alkaline treatment to the surface of the
35
36 samples, without damaging the material. In our case, we treated the aerogels with NaOH (1M) for 30 s at
37
38 room temperature. A porous surface layer adheres strongly to the aerogel, as the result of the increased
39
40 number of OH terminating groups on the surface. It is well-known that the presence of OH groups seems
41
42 to facilitate the bonding of the aerogel to the apatite layer. It was expected that the use of the alkaline
43
44 treatment would makes the aerogel surface hydrophilic. This condition plays a very important role in the
45
46 formation of the apatite. After this treatment, the samples were gently washed in distilled water and
47
48 dried in a desiccator for 24 h.
49
50
51

52
53 The composites were designated in the style S20Ca5x. The values 20 and 5 refer, respectively, to the
54
55 PDMS and Ca content of the composite matrix; x indicates that the TEOS:MTES volume ratio is x:(10-
56
57 x).
58
59

60 **2.2. Bioactivity test**

61
62
63
64
65

1 In order to evaluate the bioactivity, the aerogels previously treated with NaOH were immersed in
2
3 sterile polyethylene boxes containing 35 ml of SBF (Table I) at 37 °C for 25 days according to the
4
5 procedure proposed by Kokubo *et al.* [18]. The SBF was prepared by dissolving reagent grade NaCl,
6
7 NaHCO₃, KCl, K₂HPO₄·3H₂O, MgCl₂·6H₂O, CaCl₂, Na₂SO₄ in distilled water, and buffering the solution
8
9 to pH 7.4 with tris-hydroxymethyl-aminomethane ((CH₂OH)₃CNH₃) and 1.0 M HCl at 37 °C. Then the
10
11 aerogels were rinsed with distilled water and dried in a desiccator for 24 h.
12
13
14

15 The Kokubo's solution contains the inorganic components of the human blood plasma in similar
16
17 concentrations. Several authors report that *in vitro* experiments with Kokubo's solution can
18
19 satisfactorily reproduce *in vivo* behaviour of implant materials [19].
20
21

22 **2.3. Examination of bioactivity and mechanical response**

23
24 Three composites were synthesized: S20Ca5M1, S20Ca5M5 and S20Ca5M9. They were characterized
25
26 structurally and texturally, and their bioactive and mechanical behaviours were evaluated to study the
27
28 influence of the MTES content on the performance of the composite.
29
30
31

32 The thermogravimetric (TG) study was carried out in a Setaram Setsys 1750 by heating the samples in
33
34 air from 25 °C to 1000 °C at 10 °C/min. The average pore diameter and surface area of the composites
35
36 were determined by N₂ adsorption/desorption isotherms at 77 K carried out in a Sorptomatic 1990 unit
37
38 (CE Instruments).
39
40

41 To evaluate the bioactivity, the formation of apatite-like layers on the sample surfaces was monitored
42
43 by scanning electron microscopy (SEM) in a FEI Sirion electron microscope coupled to an EDAX
44
45 Genesis system. The Fourier Transform Infrared (FTIR) spectra of the aerogels were recorded before
46
47 and after soaking, using a Bruker Vertex70 spectrophotometer with a resolution of 4 cm⁻¹ in the 2000 -
48
49 400 cm⁻¹ region. Pellets were prepared by grinding the samples in an agate mortar and then mixing the
50
51 powder with anhydrous KBr in a weight ratio of KBr:sample=100:1.
52
53
54

55 The X-ray diffraction pattern (XRD) measurements were performed using a Bruker AXS D8 Advance
56
57 diffractometer by the step-scanning method with Cu K_α radiation, a scan range from 20 to 50° 2θ, with a
58
59 step of 0.2°, and a counting time of 1s per step; the instrument was operated at 40 kV and 40 mA.
60
61
62
63
64
65

1 The strains at failure of the aerogels were evaluated at room temperature under compression using an
2
3 AG-I machine (Shimadzu); the Young's moduli were calculated from the slope of the initial linear elastic
4
5 portion of the stress-strain curve. The S20Ca5M1 sample has been submitted to a creep test [20,21]
6
7 applying 1.00 MPa for 4 h at room temperature. Creep compliance data were calculated directly,
8
9 following the standard procedure [22,23], as the strain divided by the applied stress.
10

11 **3. Results and Discussion**

12
13 The thermograms of the S20Ca5M1, S20Ca5M5 and S20Ca5M9 samples are represented in Figure 1.
14
15 The three composites present a sharp weight loss due to the carbonation of the organic polymer enduring
16
17 after supercritical ethanol drying. The weight loss is greater in the S20Ca5M5 sample because the
18
19 polymer is better encapsulated in the silica network formed by the TEOS and the MTES. This weight
20
21 loss is 23 % whereas for the S20CaM1 sample the loss is 16 %.
22
23
24
25

26
27 These materials exhibited characteristics of type IV and V isotherms (Figure 2) that correspond to
28
29 mesoporous materials, in which the N₂ adsorption at low pressure is produced by the formation of
30
31 multiple layers. At high pressure, the adsorption is caused by capillary condensation, which is
32
33 characterised by a clear hysteresis loop occurring in the mesoporous range. A transition is observed in
34
35 the hysteresis loops from H4 to H3 type (which admittedly are quite similar) which indicates the
36
37 presence of pores formed by flattened particles and slit-shaped pores [24]. The type H4 loop was
38
39 reported for MCM-41 that exhibited particles with internal voids of irregular shape and broad size
40
41 distribution (between 5 and 30 nm) [25]. This loop seems to be due merely to the existence of
42
43 mesopores formed by the organic phase embedded within the inorganic phase containing relatively few
44
45 micropores. Microporosity is a characteristic of the silica aerogels prepared with ultrasounds (known as
46
47 sonogels) [26], which is modified by the presence of the organic phase [27,28]. The textural properties
48
49 extracted from the data analysis are given in Table II.
50
51
52
53

54
55 Figure 3 presents SEM images and EDS spectra of the surface of hybrid S20Ca5M1 after immersion in
56
57 SBF for 25 days. A layer covers the surface (Figure 3a). As the magnification increases, rough spherical
58
59 shaped particles can be observed (Figure 3b and Figure 3c), formed by fine lamellar crystals (Figure 3d).
60
61
62
63
64
65

1 A semi-quantitative yield analysis indicates a Ca to P ratio of 1.70, almost the same composition as
2
3 apatite [29,30]. The S20Ca5M5 and S20Ca5M9 samples did not show significant bioactivity.
4

5
6 The FTIR spectra of the S20Ca5M1 sample before and after soaking in SBF are shown in Figure 4a
7
8 and Figure 4b, respectively. The bands at 450 cm^{-1} are characteristic of O—Si—O bending vibration
9
10 [31]. The bands at 1268 and 803 cm^{-1} are assigned to Si—CH₃ bond of PDMS [32] and MTES [6,33],
11
12 the band at 850 cm^{-1} is due to TEOS-PDMS copolymerization [34]. In Figure 4b, after soaking the
13
14 composite for up to 25 days in SBF, the bioactive aerogel showed a typical doublet at 564 and 603 cm^{-1} ,
15
16 which can be ascribed to P—O bending vibration [35,36]. A specific peak of HPO_4^{2-} [37] appears at 875
17
18 cm^{-1} .
19
20
21
22

23 Figure 5 displays the diffracted X-ray intensities of the S20Ca5M1 composite after soaking in SBF for
24
25 25 days. The characteristic diffraction peaks of hydroxyapatite (HAp) were identified, confirming the
26
27 bioactivity of this material [38,39,40,41] in agreement with the SEM, EDAX and FTIR observations.
28
29

30 Table III gives the values of both the Young's modulus and rupture strengths from the uniaxial
31
32 compression test. The rupture modulus and Young's modulus increase as the content of MTES
33
34 increases. For a better characterization of the visco-elastic behaviour of the material, we have calculated
35
36 the Young modulus in three different intervals of the stress-strain curves: a) in the elastic range (strain
37
38 between 0 and 0.10), b) in the middle of the visco-elastic behaviour (0.10 - 0.30) and, finally, c) near the
39
40 rupture limit (0.30 - rupture strain). It can be seen that samples show an elastomer-like behaviour, as the
41
42 Young's modulus increases as the strain approaches the rupture limit, attaining a value as high as 117
43
44 MPa for the S20Ca5M9 sample. The three types of samples studied in this work present values of the
45
46 Young's and rupture modulus in the standard range for human cancellous bone, i.e. 50 - 500 MPa [42,
47
48
49
50
51
52
53 43].

54 A bi-exponential fitting of the creep compliance of the S20Ca5M1 sample was carried out and is
55
56 represented in Figure 6. The satisfactory agreement between experimental data and theoretical
57
58 expression indicates the existence of two different mechanisms of the time response. The exponents
59
60 characterize the short-term and long-term responses. Their values are approximately 1500 s and 20000 s,
61
62
63
64
65

1 respectively, and the creep compliance value is close to 0.11 GPa^{-1} , quite similar to that of the pure
2
3 silica aerogel measured by nanoindentation (0.1 GPa^{-1}) [44]. This can be explained on the basis of a
4
5 response mechanism controlled by the inorganic phase skeleton.
6
7

8 **4. Conclusions**

9

10 The specific features of these hybrid aerogels: weight loss, specific surface and mechanical properties
11
12 can be directly attributed to the MTES content. The treatment to induce bioactivity proved to be
13
14 appropriate for obtaining bioactive materials. The aerogel S20Ca5M1 is expected to find application as a
15
16 new type of bioactive material, having demonstrated an excellent apatite-forming ability in SBF, and
17
18 mechanical properties analogous to those of human cancellous bone.

Table II. Textural data for the composites.

Aerogel	BET surface area (m ² /g)	Pore volume (cm ³ /g)	Average pore diameter (nm)
S20Ca5M1	856	3.11	9.8
S20Ca5M5	582	1.02	7.5
S20Ca5M9	271	0.69	10

1 Table III. Mechanical data for the composites.
2
3

Sample	Rupture modulus (MPa)	Young's modulus (MPa)		
		A	B	C
S20Ca5M1	4	11	6	10
S20Ca5M5	5	29	38	61
S20Ca5M9	28	84	58	117

9 Strain intervals (%)

10 A: 0-10, B: 10-30, C: 30-Rupture
