Exalted photocatalytic activity of tetragonal BiVO₄ by Er³⁺ doping through a luminescence cooperative mechanism†

Sergio Obregón, ∗a,b Soo W. Lee ∗b and Gerardo Colón ∗a

Er-doped BiVO₄ are synthesized by means of a surfactant free microwave assisted hydrothermal method having good photoactivities under sun-like excitation for the degradation of methylene blue. From the structural and morphological characterization, it has been stated that the presence of Er³⁺ induces a slight stabilization of the tetragonal phase, probably due to its incorporation in the BiVO₄ lattice. The best photocatalytic performances were attained for the samples with Er³⁺ content higher than 3 at%. The occurrence of the Er³⁺ doped tetragonal BiVO₄ clearly induces higher photocatalytic activities. The existence of a luminescence process has been related with the enhanced photoactivity observed.

Introduction

Heterogeneous photocatalysis is regarded as a green route to afford pollutant degradation. Moreover, other different green chemistry reactions such as water or CO₂ photoreduction to produce H₂ or biofuels are now gaining interest. In this sense, the utilization of solar light as efficiently as possible has been largely pursued. Towards this aim, different approaches have been traditionally followed, based in all cases on the visible light photon absorption improvement. This way, the photonic efficiency will be enhanced by simply increasing the number of useful photons available. For this scope, the modification of TiO₂ by cation doping has been extensively reported with controversial results in certain cases. Other strategies recently reported involve the development of novel alternative materials to traditional TiO₂ capable of using sunlight as a green energy source.3

In this sense, bismuth vanadate has been found to be a promising candidate used for organic contaminants decomposition as well as in CO₂ reduction under visible-light irradiation.3–7 BiVO₄ appears in three main crystalline phases: monoclinic, tetragonal zircon, and tetragonal scheelite. Among the above three crystal phases, monoclinic BiVO₄ (m-BiVO₄) is the best visible-light-driven photocatalyst due to its lower band gap value (ca. 2.4 eV), while the photocatalytic activity of tetragonal BiVO₄ (t-BiVO₄) was reported to be negligible.8–11 For this reason, different synthetic methods have been recently proposed for obtaining the photoactive monoclinic phase.12–14

A novel challenging composite configuration would consist of the assembly of the photocatalytic material with a luminescence material.2 Within this novel configuration, the improvement is reached by increasing the number of incoming photons with adequate energy which can be absorbed by the photocatalyst. Among various up-converting nanomaterials, Er³⁺ constitutes an interesting option for this purpose which could be excited by visible-light or NIR, showing luminescence in the visible and ultraviolet regions.15,16 In a recent paper, we described the assembly of TiO₂ with such up-converting doping cations.17 From those results, we proposed that the presence of Er³⁺ doping into TiO₂ as host matrix favors a double electronic and luminescence mechanism, under UV and NIR excitation respectively.

Experimental details

The BiVO₄ samples were prepared by a microwave-assisted hydrothermal method. Firstly, 5 mmol of Bi(NO₃)₃·5H₂O (Sigma-Aldrich, ≥98.0%) and stoichiometric amounts of Er(NO₃)₃ (from 0.25 to 4 at%) were dissolved in 10 mL of glacial acetic acid at room temperature. A second aqueous solution was prepared by dissolving the corresponding stoichiometric amount of NH₄VO₃ (Sigma-Aldrich, ≥99.0%) in 60 mL of hot distilled water. Afterwards, the ammonium metavanadate solution was added to the bismuth nitrate

†Electronic supplementary information (ESI) available: Preparation and photocatalytic activity of BiVO₄ by the mw-assisted hydrothermal method. See DOI: 10.1039/c3dt51923f
aqueous solution and the process was accompanied with vigorous stirring. The pH of the obtained suspension was adjusted to 9.0 by adding concentrated NH₄OH (13 mol L⁻¹). The slurry was transferred to a Teflon vessel and heated under microwave irradiation using a microwave reactor (model MWO-1000S, EYELA; Japan). The temperature was fixed at 140 ºC with a maximum variable power of 195 W for 30 minutes (being the optimum microwave treatment time, see ESI†). The obtained precipitate was then cooled until room temperature, filtered and repeatedly washed and dried overnight at 120 ºC. Afterwards, thus obtained samples were submitted to a further calcination treatment at 300 ºC for 2 h. A reference tetragonal BiVO₄ sample was prepared by following the synthetic route above described but using triethylamine (TEA) as a precipitating agent.

**Results and discussion**

The preparation of BiVO₄ by the mw-assisted hydrothermal method leads to the monoclinic phase structure (PDF 14-0688) in all cases (see ESI†). Upon Er³⁺ doping, it can be observed that the monoclinic phase is attained for dopant content below 2 at%. For higher Er contents, a mixture of the tetragonal phase arises (PDF 14-0133), being the main crystalline phase for systems with Er³⁺ content higher than 3 at%. This tetragonal stabilization by lanthanide doping has been similarly described by other authors. Since the tetragonal phase was denoted as the low temperature structure of BiVO₄, the occurrence of such doping ions in the BiVO₄ structure seems to retard the monoclinic appearance.²⁵ As can be observed from XRD pattern evolution, this effect is evident for Er³⁺ contents higher than 3 at%. No traces of Er₂O₃ were found even for samples with higher doping loading (Fig. 1). In this sense, the effectiveness of erbium doping was stated by Rietveld analysis it can be pointed out that at lower Er³⁺, the m-BiVO₄ structure is not significantly affected (Table 1).

The cell volume of the monoclinic structure slightly grows as the Er³⁺ content increases. From this behaviour, it can be inferred that in spite of the lower ionic radius of Er³⁺ vs. Bi³⁺ (103 pm and 117 pm respectively), the substitution of Bi³⁺ by Er³⁺...
Er$^{3+}$ ions is not taking place. Therefore, Er$^{3+}$ would be placed interstitially causing this small cell expansion. When the tetragonal phase is present, Er$^{3+}$ produces a clear diminution of the cell volume (Table 1). Such a volume contraction could indicate the effective substitution of Bi$^{3+}$ by Er$^{3+}$ in the tetragonal structure.

In accordance with the literature, the surface areas obtained for all samples are significantly low (Table 1). However, systems with a tetragonal phase show slight increase in surface areas. At the same time, two clear absorption edges can be noticed when the tetragonal phase is present, leading to 2.4 eV and 2.9 eV band gap values for the monoclinic and tetragonal phases, respectively (Table 1).

The Raman spectra of this series also support the presence of a single monoclinic phase at lower Er$^{3+}$ content (Fig. 2). For higher lanthanide loading, strong luminescence bands correspond to the fluorescence emission of Er$^{3+}$ due to the excitation of green laser (532 nm) (Fig. 2a). It is worth noting that the presence of strong luminescence is correlated with the occurrence of the tetragonal structure. It can be inferred that when Er$^{3+}$ is substituting Bi$^{3+}$ in the vanadate matrix, the luminescence emission occurs. In this sense, it has been reported that trivalent metal orthovanadates show excellent performances as matrices for luminescent lanthanides due to efficient energy transfer (ET) from the VO$_4^{3-}$ absorption to the excited states of the activators (Ln$^{3+}$).\textsuperscript{21}

The Raman spectra registered by 780 nm laser excitation (Fig. 2b) clearly denote the monoclinic to tetragonal transition observed by $\nu_3$ (V–O) band shift and the disappearance of the $\delta$ (VO$_4^{3-}$) doublet of the monoclinic phase.\textsuperscript{10} In this case, small luminescence bands from Er$^{3+}$ excitation by red laser can also be observed.

The morphology of BiVO$_4$ has been extensively reported to be dependent on the preparation route.\textsuperscript{22} In our case, bare BiVO$_4$ shows a rod-like morphology (Fig. 3a).

As Er$^{3+}$ is incorporated, the length of these rods seems to diminish (Fig. 3b–d). When tetragonal phase appears, a clear change in the morphology is observed and particles exhibit a needle-like structure. Thus, for the highest Er-doped system the acicular morphology has almost disappeared (Fig. 3e). The slight increase in the surface area could therefore be correlated with this change in the morphology and the diminution of particle size. Such evolution is directly associated with the incorporation of Er$^{3+}$ and the subsequent phase transformation from monoclinic to tetragonal.

In Fig. 4 we show the photocatalytic activity of the studied systems. It is worth noting that the preparation of BiVO$_4$ by the mw-assisted hydrothermal method leads to higher photoactivity with respect to that prepared by the simple coprecipitation method. Moreover, the incorporation of Er$^{3+}$ also leads to a

$^a$ Measured by X-ray fluorescence.
slight progressive enhancement till 2 at% content. This improvement could be described in terms of classical doping theory in which dopant would help the charge separation till its concentration is detrimental and promote the recombination process. No luminescence emission is observed for these samples. Then, the appearance of the tetragonal phase significantly improves the photocatalytic performance of systems.

Thus, for Er\textsuperscript{3+} content higher than 3 at%, a drastic increase in the reaction rate is observed (Fig. 4). The optimum photoactivity was attained for systems with 4 at%, being four times higher than that corresponding to bare BiVO\textsubscript{4}. It is worth noting that for such photocatalysts the tetragonal phase is mainly present (96%).

In order to elucidate the effect of Er\textsuperscript{3+} in this t-BiVO\textsubscript{4}, we have prepared undoped t-BiVO\textsubscript{4} by a similar mw-assisted hydrothermal method. The sample obtained shows a predominant tetragonal phase (95%), presents a bar-like morphology and a surface area of 4 m\textsuperscript{2} g\textsuperscript{-1} (Fig. 5). Taking into account these structural and surface features, this reference system can be directly compared to Er-BiVO\textsubscript{4} (4 at%). The MB degradation reaction rate obtained for this t-BiVO\textsubscript{4} is $3.0 \times 10^{-4}$ s\textsuperscript{-1}. There exists a slight enhancement in the photoactivity with respect to undoped m-BiVO\textsubscript{4} ($1.5 \times 10^{-4}$ s\textsuperscript{-1}). Such an improvement could be explained by considering the higher surface area of t-BiVO\textsubscript{4} and perhaps the presence of the small amount of the monoclinic phase (5%). Indeed, the presence of a monoclinic–tetragonal heterojunction was recently reported and exhibits better photocatalytic performance. Thus, Fan et al. reported that the particular m–t heterostructured BiVO\textsubscript{4} is expected to promote the separation of photoinduced electron–hole pairs. In spite of this, the exalted performance of Er-doped t-BiVO\textsubscript{4} ($6.0 \times 10^{-4}$ s\textsuperscript{-1}) with respect to the t-BiVO\textsubscript{4} ($3.0 \times 10^{-4}$ s\textsuperscript{-1}) system cannot be attributed only to a surface area contribution or the presence of a small amount of monoclinic phase. Indeed, much research has shown that the surface area would play a key role in the final photocatalytic performance. As is widely reported, this is not the case for BiVO\textsubscript{4} systems, for which structural features are the controlling parameters.

In a recent study, we have proposed the Y\textsuperscript{3+} doping of BiVO\textsubscript{4}. In that paper, we stated that the incorporation of yttrium at loading higher than 3 at% into the BiVO\textsubscript{4} structure leads to a clear stabilization of the tetragonal phase and the increase of the surface area. However, for doping concentrations higher than 3 at% the photoactivities tend to decay. Indeed, this is the evolution of Er–BiVO\textsubscript{4} for doping levels higher than 2 at%, just before tetragonal phase appears. This behaviour could be attributed to a detrimental effect of dopant concentration by increasing the recombination processes. All these facts would indicate that erbium doping would affect the
reaction mechanism in a different particular way when the tetragonal phase is present. On this basis, and considering the developed luminescence effect observed for Er-doped t-BiVO₄ a cooperative mechanism could be envisaged.

Lower photoactivities reported in the literature for t-BiVO₄ were explained considering the wider band gap for this phase. Thus, in our case, the observed photoluminescence in the visible region upon illumination with 532 nm laser points out the participation of such luminescence processes in the overall mechanism. According to previous reports, the emission bands around 318.7 and 320.1 nm could be observed in Er⁴⁺-doped compounds under the pumping of 486.5 and 542.4 nm (or 548.8 nm), respectively.²⁹,³⁰

Moreover, it has been also reported that violet (405–420 nm), blue (436–442 nm) and green (525–575 nm) up-conversion luminescence were simultaneously observed upon excitation at 652 nm.³¹ This way, Er⁴⁺-doped t-BiVO₄ could improve the photoefficiency by increasing the absorbed photons.

In Fig. 6, we show the photoluminescence spectra for different Er⁴⁺ doped systems upon excitation at 523 nm and 655 nm.

**Fig. 6** Photoluminescence spectra for different Er⁴⁺ doped systems upon excitation at 523 nm and 655 nm.

“up-conversion” mechanism could be envisaged. A similar effect was already observed for Er³⁺ doped TiO₂, for which an “up-conversion” mechanism would be responsible in part for the better photocatalytic behaviour.¹²

**Conclusions**

We have prepared highly efficient Er doped BiVO₄ photocatalytic systems by means of the microwave assisted hydrothermal method. The presence of Er³⁺ ions induces the appearance of the tetragonal phase at higher loading that might be incorporated into the structure by Bi⁵⁺ substitution. This is the first time that tetragonal BiVO₄ is reported to exhibit better photocatalytic performance than the monoclinic one. Such improved photoactivity of the t-BiVO₄ under sun-like irradiation was correlated to the occurrence of a luminescence process which takes place for such a structure. The cooperative mechanism induces an unexpected photocatalytic enhancement by increasing the number of the adequate photons. This novel approach opens a wide field of applications to other photocatalytic materials having good luminescence properties as host matrix such as molybdates, tungstates or phosphates.
